## Abstract

This project focussed on the manufacturability of Pork Sausage Links in Brine and Creamed Ground Beef as function of selected process and packaging parameters.

Moisture entrapment in the seal area is the primary cause for seal defects. Lower line speeds and/or lower fill temperatures were identified as solutions to reduce these type defects. To a much lesser degree did vacuum create seal defects and was a function of the type product that was being filled. Higher fill weights in combination with lower vacuum were identified to as solutions to reduce this type defect.

The flange thickness variation of the tray had a significant impact on the required seal conditions. An increased variation in the flange thickness requires longer seal times, but reduces the maximum throughput rate of the sealer. Improving the flange thickness variation needs to be considered to increase the line capacity to the target rate to 20 trays/min.

The thermal process is the most likely bottle neck of the manufactures process. Retort studies demonstrated significant reductions in process times by utilizing rotational retort processes. The cook time for Pork Sausage Links in Brine was reduced by 24% and for Creamed Ground Beef by 58%.

# **1. Results and Accomplishments**

## **1.1. Introduction and Background**

Earlier Manufacturability Studies examined Polymeric Tray Pack production at fixed production rates which were either based on semi-commercial rates (Star Foods: 2 – 4 trays/min) or conservative non-optimized rates (Rutgers FMTF: 9 – 10 trays/min). However, the commercial-scale Heat Sealer at Rutgers routinely processes non-military polymeric trays at 15/minute and the heat sealer-only portion of the production line is rated at 30 trays/minute. Actual commercial operating rates would be expected to have significant impacts on production economics and the impact sustained by any limiting specification levels.

Since the inception of the Tray Pack Ration, the product has been processed and packaged in a heavy metal tray shaped can with a double seamed metal lid. As a result of the Process Action Team at DSCP, The Polymeric TrayPack Program at NATICK and CRAMTD Short Term Project STP #10 at the Rutgers University CAFT, an alternative package was developed utilizing a polymeric tray body and a laminated foil and polymer lidstock. This alternative package was necessary due to a declining supplier base for the metal tray can and lid (one supplier) and various problems with the interior coating of the cans. The square metal can was also difficult to open and presented a safety hazard from the sharp edges on the lid after opening. Manufacturability studies performed both Star Food and the CAFT FMT Facility plus two production tests (one at Wornick and one at Stegner Foods) revealed product-compatibility issues with the specifications as adapted from the metal can for the polymeric tray.

The polymeric tray has been field tested by both the Army and the Marine Corps and has been found to be acceptable. Shelf life testing by SBCCOM has determined that the polymeric tray will provide similar quality to the metal tray over a 36 month period. DSCP has outlined its plans to phase in the polymeric tray during the next procurement cycle. In order for that phase-in to work smoothly and successfully, each of the specifications must be reviewed and tested for revision to the polymeric tray. The maximum processing parameters for the polymeric tray have never been established, nor has alternate processing techniques such as rotation during retorting been reviewed. The polymeric tray replacement for the metal tray-can is an urgent program of great importance to the Military Services, especially since past metal cans are showing evidence of premature deterioration.

## **1.2. Objectives**

This proposal is to perform a Short Term Project (STP) under the CORANET Contract, SP0103-96-D-0016. The objective of which is to verify and test the specification requirements for production of thermostabilized items in polymeric trays. The specification requirements will be tested to determine the attainable limits imposed by process capability in order to maximize production while maintaining the current quality of the product for a period of 36 months and the performance of the package at the level to which the services are now accustomed.

## **1.3. Results and Conclusions**

This project focussed on the interactions that selected product, process and packaging variables have on packaging and retort efficiencies. The project used Pork Sausage Links in Brine and Creamed Ground Beef as the two test products.

It was concluded that moisture entrapment in the seal area is the primary cause for seal defects. This moisture entrapment was either caused by splashing during filling (low viscosity products) or by condensation of headspace moisture in the seal area (hot fill products). Lower line speeds and lower fill temperatures were identified as solutions to reduce these type defects. To a much lesser degree did vacuum

create seal defects and could be correlated to the type product that was being filled. Higher fill weights in combination with lower vacuum were identified as solutions to reduce this type defect.

It was also concluded that the flange thickness variation had a significant impact on the sealing conditions that needed to be used. Larger variations in the flange thickness required longer seal time in order to assure that the seal width exceeded the minimum specification requirements. Seal times of 3.5 seconds were found to be adequate to produce a consistent wide seal. Longer seal times however reduced the maximum throughput rate of the sealer to 15 trays/min. Further investment in reducing the flange thickness variation should be considered to increase the line capacity once the packaging line speed becomes the bottle neck of the process.

In the economic analysis, it was determined that the thermal process was currently the most likely bottle neck in a manufactures process. Retort studies clearly demonstrated the very significant reductions in process times that can be obtained by utilizing rotational retort processes. The cook time for Pork Sausage Links in Brine was reduced by 24% and for Creamed Ground Beef by 58%. The racking system that was developed for this tray was able to support the tray during these rotating retort processes without creating abrasion type defect in the seal area.

## **1.4. Recommendations**

- ❑ Evaluate the impact of anomaly type defects in the seal area caused by moisture on the seal strength. Relaxation of the specification requirements in this area will have significant impact on the manufacturability of these type products
- ❑ Evaluate the impact of Residual Gas on the shelf life and package integrity. Relaxation in this area will have a significant impact on the manufacturability of these type products.
- ❑ Asses with producer of tray the reasons for flange thickness variation and possible solutions to reduce the variation which can lead to decreased seal time and increase throughput rates
- ❑ Evaluate different nozzles designs that prevent moisture contamination of the seal area
- ❑ Evaluate systems that would accommodate hot fill products without condensation of headspace moisture in seal area. Hot fill products will reduce process times and increase line capacity.
- ❑ Evaluate additional products to identify additional filling, sealing and retort issues and develop guidelines for resolution.

## **2. Program Management**

The project was awarded on May 24, 2000 under contract SP0103-96-D-0016, Delivery Order 0017 with a total obligation of \$240,050. Performance period for this delivery order was set for 11 month (April 24, 2001).

The following modifications were issued:

April 18, 2001	0017/01	performance period is extended from 4/24/01 to 5/24/01 at no additional cost
May 7, 2001	0017/02	performance period is extended from 5/24/01 to 9/30/01 at no additional cost, and reallocation of budget as outlined in letter from Rutgers, dated April 19, 2001
Sept 30, 2001	0017/03	performance period is extended from 9/30/01 to 10/31/01 at no additional cost.

Reason for the first two modifications was due to the excessive variability in flange thickness of the tray produced by Rexam, requiring new trays to be produced. Production of these trays was however delayed due to delays in production contract awards. The third extension was awarded to complete the final report

### **3. Short Term Project Activities**

#### **3.1. Production System Analysis**

The objective of this task was to perform a production systems-analysis including subsystems for filling, sealing and retorting of product in polymeric trays and determine the impact of production rates and investments on cost per unit.

The analysis was performed by building a production model within an Excel Spreadsheet of a typical Polymer Tray Pack Production System including filling, sealing, and retorting and use data available from the manufacturability studies performed earlier at Rutgers. The model calculated the cost per unit for production of polymeric trays based capital investment, production rates, production yields, production efficiencies and resource requirements. Case studies, using various assumptions, were used to determine the impact of these assumptions on the unit cost.

The economic model and analysis clearly demonstrated that the retort operation is the most capital intensive part of the process. More than likely the available retort capacity in a plant will dictate the packaging line speed. Therefore, the emphasis of this project needed to focus primarily on increasing the capacity retort process. As a secondary objective, the project needed to focused on the packaging line speed, to determine if 20 trays per minute could be achieved and how process yield would be affected as function of selected product, process and packaging parameters.

An Interim Program Review was held on August 11, 2000, with the CORANET Program Manager, members of the Joint Steering Group and Industry representatives. Based on these case studies recommendations were made regarding a detailed experimental study for the retort and the packaging processes. The recommended variables for retorting studies were rotation versus static cooking, headspace, and retort rack configurations. The recommended variables for filling/sealing experiments were fill temperature, viscosity, fill weight, vacuum, seal time and line speed.

Details of the economic model and analysis, including the various case studies are documented in Technical Working Paper #215.

#### **3.2. Process and Product Development**

As a first step, a complete process and product development activity was executes to determine formulations and procedures that would yield acceptable product. Samples of product were submitted to Natick to confirm acceptability.

The Creamed Ground Beef required significant product development activities to ensure that the product was stable in a rotating retort. Initial samples tended demonstrate fat separation during the retort process. Careful selection of ingredients in combination with lean ground beef resulted in product that was found to be acceptable.

Once the product formulation and process descriptions were identified, various packaging and food ingredients were acquired to support the experimental and production phases of this project. Each of the technical working papers (TWP 213, 214, 216, 217 & 218) document the suppliers of the main ingredients and packaging materials.

#### **3.3. Retort Variable Study**

The objective of this variable study was to determine the effect of residual gas, product viscosity, rack configuration and rotational speed on retort cycle times. Two products: Pork Sausage in Brine and Creamed Ground Beef were used for this study. It was concluded that a rotational process significantly

decreased the average required cook time of Pork Sausage in Brine by 24% and of Creamed Ground Beef by 59%.

Rotational retort process can enhance both the external heat transfer as well as the internal heat transfer of the tray. The external heat transfer is enhanced by increased water flow around the container. The internal heat transfer can be increased if the headspace gas can be forced to move through the liquid phase of the product and thus inducing a "forced convective flow". Increased headspace, up to a certain limit, will increase the effectiveness of this forced convection. The movement of the headspace through the liquid phase and its ability to induce forced convective flows is however impacted by the viscosity of the liquid phase and the rotational speed of the retort. Very viscous products, such as pumpkin pie, are too viscous and rotation can not force the headspace gas through the product.

Rotation retort speed needs to be optimized to obtain maximum efficiency of the forced convective flows. Maximum efficiency is obtained when the air bubble cuts through the liquid phase and not along the perimeters of the tray (=speed too low) or not move at all (=speed too fast).

Detailed results of the retort studies are documented in three technical working papers (TWP-213, 214 & 216). A summary of these studies is given in the sections below.

### 3.3.1. Pork Sausage Links in Brine

Pork Sausage Links in Brine has a low viscous liquid. The rotational speed (5 & 15 rpm) seemed to be less effective than seen in the other product. In matter of fact, higher residual gas resulted in slower heat transfer rates in the rotational process. This seems to indicate that the air bubble was not able to cut through the liquid phase, but instead traveled along the perimeter of the tray. In these cases, residual gas can act as an insulator rather than an agitator. Natural convective flows of the brine seem to be sufficient in transferring the heat to the sausage links and the heat transfer seemed to be limited by the external heat transfer which improved when the flow of the heat transfer media was increased by using retort rotation. To obtain maximum performance, this product should be packed off with a relative low residual gas level and be processed with maximum water flow in between the container.

Program	Res Gas	Cook Time	% Change
Static	150	31.2	0%
Static	350	33.9	+6%
Rotation	150	23.8	-24%
Rotation	350	26.0	-17%

Table #1: Average Cook Time and Cook Time Reduction for Pork Sausage Links in Brine

### 3.3.2. Creamed Ground Beef

Creamed Ground Beef was made with two different sauces: one low to medium viscous sauce (T-T) and one medium to high viscous sauce (P-W). Rotation speed with high residual gas was quite effective in increasing the heat transfer rate, indicating that the air bubble cut through the sauce.

The low to medium sauce (T-T) was made with a special starch, THERMTEx<sup>®</sup> starch from National Starch, that was developed specifically for retort applications. This starch does not develop its full viscosity at batch preparation temperatures (180 F), but requires retort temperatures (240-250F) to fully

develop its viscosity. This increases the heat transfer rates in rotational retort processes, as the headspace gases are more effective to induce the forced convective flows in the sauce.

Use of the , THERMTEx® starch, in combination with rotational retort processing and higher residual gas, resulted in very significant reduction in average required Cook Time (59%).

Program	Res Gas [cc]	Starch [-]	Cook Time [min]	% Change [-]
Static	150	P-W	75.8	0%
Static	150	T-T	78.4	3%
Static	350	P-W	87	15%
Static	350	T-T	92.3	22%
Rotation	150	P-W	53.3	-30%
Rotation	150	T-T	39.4	-48%
Rotation	350	P-W	44.1	-42%
Rotation	350	T-T	30.9	-59%

**Table #2: Average Cook Time and Cook Time Reduction for Creamed Ground Beef**

It should be noted that, while the heat transfer rate of products with medium viscosity sauces and gravies can be improved in rotational retort process by increasing the residual gas, static retort processes should be produced with a low residual gas level for optimal performance.

### **3.4. Packaging Variable Study**

The objective in this task was to determine the interactions between variables such as line speed, product fill temperature, product viscosity, fill volume, vacuum, seal time, residual gas and seal defects.

At the start of the study, it was discovered and documented that the quality of the flange thickness had an over riding effect on the quality of the seal. Increased variability of the tray flange thickness led to increased variation in the seal width and localized narrow and unacceptable seals. To overcome this defect, seal times needed to be increased, in order to melt away the thick parts of the flange in order to seal also the thinner parts of the flange. Increased seal time, however, had a direct effect on the maximum through put rate of the packaging line. Table #3 displays the required seal time parameter as function of the tray flange quality. Table #4 displays the effect of seal time on the maximum throughput that can be achieved on the Raque Heat Sealer as function of the seal time and vacuum time

Tray ID	Tray Weight (gram)	Flange Thickness (mil)	Range (mil)	Seal Time (sec)
7991 (6/20/00 3A)	155.5/5.6	68.1/4.1	14	2.5
7991 (6/16/00 4X)	156.7/0.3	69.3/6.8	20	4.5
7991 (6/15/00 4A)	155.4/0.7	66.0/8.1	25	6.5
8950 (Jan 01 #456)	155.9/0.4	72.1/6.8	20	3.5-4.5
9743 (5/25/01 B)	156.2/0.2	67.1/6.0	18	2.5-3.5
9743 (5/26/01 A)	155.6/0.3	67.0/5.8	17	2.5-3.5

**Table #3: Required Seal Times as function of Flange Thickness Variation**

Vacuum Time	0.2 sec	1.0 sec	1.5 sec
Seal Time			
2.5 sec	24	19	17
3.0 sec	21	17	15
3.5 sec	18	15	13
4.0 sec	16	13	12
4.5 sec	14	12	11

**Table #4: Maximum Capacity Raque Heat Sealer [trays/min] as function of Seal Time and Vacuum Time**

Because of the significant effect of flange uniformity on the seal quality, experiments were postponed till a large production run was made at Rexam that would yield a uniform population of trays from which the experiments could draw upon. This large production run was delayed due to a delay in the release of production contracts, leading to a delay in the experiments and completion of this short term project. Trays were finally produced by the end of May.

All experiments were produced with Tray Lot ID 9743 which were produced over a two day period at Rexam Containers. A total of 384 trays with Pork Sausages Links and 778 trays with Creamed ground Beef were packed off and analyzed for seal defects as function of product, process, and package variables. Detailed results of the packaging studies are documented in technical working paper (TWP-217 & 218). The sections below are a summary of these studies.

### 3.4.1. Pork Sausage Links in Brine

Pork Sausage Links in Brine required placement of 72 sausage links inside the tray. This was a manual and labor intensive operation. Once the tray was filled with sausage, the tray was placed in the carrier of the sealer and filled with a brine solution. The consistency of brine is that of water and the liquid filling process tended to "wet" the seal area as it splashed. Therefore, the seals needed to be dried before sealing, in order to prevent anomalies in the seal area. The study determined that, under the current specifications, the packaging of this product did not lend itself to high production speeds as the seal drying became less effective and resulted into increased anomalies in the seal area. While this type of defect is classified as "minor", it has the potential to cause lot rejection. This forces the producer to remove these tray from the line and recycle the product if possible.

Product Temperature was an important factor in controlling seal defects. Trials were made that used refrigerated sausages and a hot brine fill. The resulting product had an average product temperature of about 120 F while it entered the sealing chamber. This led to moisture condensation in the seal area and consequently large number of anomalies in the seal, even though the seals were carefully dried before entering the seal chamber.

It was determined that longer seal times can reduce the effect of a moist seal area by melting away the top layer of the flange and pushing the molten polypropylene with the moisture to the edge of the seal. The anomaly appeared in that case in the edge of the seal. It was however difficult to determine if the anomaly is inside the first 1/16" of the seal (scorable) or if the seal started right after the anomaly (not scorable).

The US Army Natick Soldier Center has evaluated the minor anomaly and suggested that the minor anomaly, caused by moisture, should not be scored as a defect, as long as there is at least 1/8" wide seal. A

revised specification is under development. This revised specification would allow for higher line speeds and higher fill temperatures while not sacrificing packaging yield.

It was determined that vacuum and fill weight had no significant effect on the seal quality and thus the specification limit for residual gas was not causing incremental seal defects. We should however note that the sausages were completely submerged in the brine at either fill weight, an important aspects as we will discuss later. It should also be noted that higher fill weights, require less vacuum to be applied in order to meet the finished product residual gas specification. This will have a positive effect on the sealer capacity. It should also be noted that higher fill weights, while not causing additional defect on the continuous motion sealer, it might cause additional defects in an indexing heat sealer.

While the residual gas did not directly effect the packaging yield, it is still suggested that the maximum residual gas level is relaxed as will be explained later.

### **3.4.2. Creamed Ground Beef**

Creamed Ground Beef was filled in a single stage filling operation, using a single Raque piston filler. Two sauce consistencies were tried and neither one led to seal contamination, nor did the line speed or product temperature have a significant effect on seal contamination at the filling station.

The most important factor that effected the seal quality was the product temperature. Even though the seals were clean and dry entering the sealing station, condensation from the hot product caused a significant number of seal defects (anomalies). This observation was consistent with the observation noted in the Pork Sausage in Brine product.

While the type of defect that it created was classified as "minor", it's potential to cause lot rejection, forces the producer to remove these tray from the line and recycle the product if possible.

As was the case in Pork Sausage Links with Brine, longer seal times reduced the effect of moisture in the seal area by melting away the top layer of the flange and pushing the molten polypropylene with the moisture to the edge of the seal. The anomaly appeared in that case in the edge of the seal. It was, however, difficult to determine if the anomaly is inside the first 1/16" of the seal (scorable) or if the seal started right after the anomaly (not scorable).

Contrary to the Pork Sausage product, it was determined that fill weight had a significant effect on the seal quality. Specification fill weight created more defects than trays filled to 100 oz. Vacuum was an order of magnitude less significant than fill weight. Strong vacuum could be pulled without causing defects in the seal area, as long as the tray was filled significantly above the specification limit. A more detailed explanation for the cause and the interaction with product characteristics will be given in section 3.6.1.3

The US Army Natick Soldier Center has evaluated higher residual gas levels and made recommendations to increase the maximum allowable level. This relaxation in specification limit will have a significant effect on the vacuum that needs to be pulled, resulting in an increase of maximum throughput rate and reduction in seal defects caused by vacuum wrinkles.

### **3.5. Sample Production for Natick**

Product Samples of both Pork Sausage Links in Brine and Creamed Ground Beef were produced in August 2001 for the benefit of the US Army Natick Soldier Center for package integrity and organoleptic analysis. Product was packed off at three different vacuum levels (10", 14" & 21" Hg), resulting in approximately

150, 250 and 350 cc residual gas. Product was sterilized in either a static retort or a rotational retort process, resulting in a total of 12 different lots. The production data is summarized in appendix 4.7.

### 3.6. Review Current Specifications

Final-performance specifications and the relationships between specification levels and production rates and yields will be reviewed in the following section. The two products that were studied under this Short Term Project will be reviewed first. In the third section, specification limits associated with the package will be reviewed

#### 3.6.1. Polymeric Tray Product Items

Table #5 lists all products that are packed off in Polymeric Half Steam Table Trays. The products can be grouped in to categories based on expected behavior during the filling and sealing process. Table #6 explains the various category descriptions. It is expected that packaging issues are somewhat category specific. However, a finer granulation of categories might be in place as the knowledge base is built.

Table #6: Category Descriptions

### 3.6.1.1. Pork Sausage Links in Brine

#### 3.6.1.1.1. Net Weight

Specification: *"The average net weight shall be not less than 90 ounces. No individual polymeric tray shall have a net weight of less than 88 ounces".*

Net weights are determined by the weight of the sausages combined with the weight of the brine. The weight of 72 sausages was extremely repeatable, as was the accuracy of the brine fill. Besides the specification limit, it is also important to note that the net weight needs match the volume of the container. An under filled container can lead to seal wrinkles and failure to meet residual gas level. An over filled container might lead to product spillage into the seal area. Trials did determine no significant impact of fill weights between 90 and 98 oz on seal defects. Therefore no problems should be encountered meeting this specification and one might consider a higher brine fill weight to reduce the vacuum level required to maintain residual gas levels below 175 cc.

#### 3.6.1.1.2. Drain Weight

Specification: *"The average drained weight shall be not less than 45.0 ounces. The drained weight of 72 intact sausage links in an individual polymeric tray shall be not less than 43.0 ounces".*

The drain weight was consistently measured at 50 oz or larger.. The burden of meeting this specification is put onto the supplier of the sausages. The vendor used for this sausage, produces that same sausage for metal tray. This producer had no problems meeting the specification limits.

**It should however be noted that the sausages are not a "commercial off the shelf" (COTS) item and that we did not identify a second producer for this product. A single source supplier can create problems in unforeseen circumstances.**

#### 3.6.1.1.3. Number of Sausages

The specification requires: *"a minimum of 72 links in each tray"*.

Because the weight of the sausages was consistent, the trays were filled based on a in-house fill weight specification rather than a count requirement. This increases the efficiency and accuracy of the filling process. This procedure maintained the count at either 72 or 73 links per tray. The burden on maintaining accurate control of sausage link weight is, again, put onto the shoulders of the supplier of the sausages. The producer had no problems maintaining accurate weight.

**Filling sausages in the tray is a time consuming operation, requiring manual labor. This filling step appears to be the rate limiting step of the operations. Achieving higher fill rates might require automation, but might only be financial attractive at high volumes.**

#### 3.6.1.1.4. Fat Content

The specification requires that: *"The average fat content of the finished product shall not be greater than 33.0 % and no individual polymeric tray shall have a fat content greater than 35.0%"*.

The fat content of the pork sausage in brine was measured at about 17%, well below the specification limits. The burden of this specification limit is put onto the supplier of the sausages. The producer had no problems maintaining the specification limits.

#### 3.6.1.1.5. Salt Content

The specification requires that: *"The salt content of any individual polymeric trays shall be not less than 1.5% nor greater than 2.5%"*.

The salt content is determined by the salt content in the sausage and in the brine. As a producer/packer the salt content in the final product is controlled by adjusting salt in the brine. No problems were encountered or are expected to maintain the salt content of the product between these two limits.

### 3.6.1.2. Creamed Ground Beef

#### 3.6.1.2.1. Net Weight

Specification reads: *" The average net weight shall be not less than 92 ounces. No individual polymeric tray shall contain less than 90 ounces."*

This is a single stage filling process. Net weights are determined by the accuracy of the filling system and the density of the product. Besides the net weight specification, it is also important to note that the fill weight should match the volume of the container. An under filled container can lead to seal wrinkles and failure to meet residual gas level. An over filled container might lead to product spillage into the seal area. Trials did determine that higher fill weights (100 oz) were feasible with actual less seal defects. Therefore, no problems are expected to meet this specification and one might consider higher fill weight. Higher fill weights would reduce the vacuum level required to maintain residual gas levels and also increase the packaging yield by generating less seal defects that are caused by the vacuum release.

#### 3.6.1.2.2. Drain Weight

The original drain weight specification (CTR January 11, 2000) required: *"an average minimum drain weight of 32.0 oz, and an individual drain weight of not less than 30 oz after retorting"*. This specification was changed in PCR-C-040, dated June 20, 2000 and reads now: *"The average drained weight shall be not less than 28.0 ounces. The drained weight of ground beef in an individual polymeric tray shall be not less than 26.0 ounces."*

In general, the drain weight is the most difficult specification to maintain and difficult to verify during the process. There are several factors that influence the drain weight. First, the precook yield and the fat content of the ground beef will have large effects on the finished product drain weight. Second, because this product is filled in a one stage filling process, the uniformity of the product blend and the segregation in the filling system can cause variation from fill to fill. Third, the drain weight test is done by using a US Standards No 8 Sieve. The size of the ground beef, the duration of the cook cycle, the quality of the beef, etc can effect the quantity of "beef fines" that go through this screen. This will affect the outcome of the drain weight test even though the right quantity of beef was added to the tray and the protein level is up to par.

**Production for commercial sales, typically does not require drain weight testing, but relies on raw material and formulation verification to ensure that label declarations are valid. Not only are drain-weight tests time consuming, they are destructive, costly and after the fact.**

#### 3.6.1.2.3. Fat Content

The original fat content specification (CTR January 11, 2000) required: *"The average fat content of the finished product shall not be greater than 10.0 % and no individual polymeric tray shall have a fat content greater than 12.0%"*. This specification was changed in PCR-C-040, dated June 20, 2000 and reads now: *"The fat content shall be not greater than 12.0 percent"*.

Fat is coming from two sources: sauce and beef, and is affected by the ratio of these two components in the final formula. The fat content in the sauce is accurately controlled (~3.7%) via the formulation. The fat of the beef can vary based on the type beef obtained and the degree of pre-cooking performed. By using "lean" beef for this product, which has a fat content of <10% before precooking, no problems should be encountered in meeting this specification.

**If regular beef is used, which can be up to 20% fat, problems might occur, not only in meeting the specification limit on fat content, but also in fat separation during the retort process. Extensive precooking of this beef might be required.**

#### 3.6.1.2.4. Salt Content

The current specification reads: *"The salt content shall be not less than 0.5 percent and not greater than 1.5 percent"*.

The salt content is controlled via the sauce. No problems were encountered nor expected to maintain the salt content of the product between these limits..

#### 3.6.1.2.5. Viscosity

The current specification reads: *"The viscosity of the gravy shall be not less than 3.5 cm per ten seconds or not greater than 8.0 cm per ten seconds"*.

The sauce viscosity of the finished product is primarily determined by the sauce viscosity before retorting, the starch used, the cook out losses from the beef during the process and the break down of starch during the retort process. Together with the drain weight, these two specifications are the most difficult factors to control. In general we were able to maintain the viscosity between 5 and 8 cm/10 seconds, but on occasion a slightly less viscous product was produced.

**Failure to meet specification indicates, either inadequate control over the process or an unnecessary tight specification range. It is suggested that a relaxation of this viscosity specification is considered in order to make the product more manufacturable.**

### 3.6.1.3. Packaging

#### 3.6.1.3.1. Residual Gas

The current specification reads: *Residual gas volume in the filled, sealed and processed tray shall not exceed 175 cc.*

To stay below this maximum limit, one needs to understand and analyze its production system and the variability that could be encountered in variables that have a direct effect on residual gas. The primary variables that effect residual gas are: vacuum applied, product fill-weight, product temperature and container volume. An increased variation in any of these variables will result in an increased variability in residual gas and therefore a lower target average value for residual gas will be required to meet the specification. This last statement is explained in the example below

For example:

- ☐ assume a normal distribution in the residual gas data
- ☐ assume less than 1% of the samples can have a residual gas level that exceeds 175 cc,
- ☐ assume a standard deviation in residual gas of 20 cc,
- ☐ hence, the target average value for residual gas should less than 128 cc.

Similar production target values for different standard deviations in residual gas can be calculated for other assumptions and some are listed in the table #7. As can be seen, the larger the variation in residual gas, or a higher degree of compliance, the lower the target value has to be set for the average residual gas level.

Std Dev Res Gas [cc]	99% R.G <175 cc	99.9% R.G <175 cc	99% R.G. <250 cc	99.9% R.G. <250 cc
10	151	145	226	220
15	139	130	214	205
20	128	115	203	190
25	116	100	191	175
30	104	85	179	160

Table #7: Production target values for residual gas for 99% and 99.9% confidence interval

The primary control variable that is used to control the residual gas is the vacuum that is pulled on the container at time of sealing. A model was built that predicts the residual gas as function of vacuum, product temperature and head space volume. Table #8 and Figure #1 display the calculated residual gas levels, assuming a headspace volume of 550 cc.

Product Temp Vacuum	70 F	120 F	170 F
0" Hg	537 cc	446 cc	275 cc
5" Hg	445 cc	362 cc	197 cc
10" Hg	353 cc	278 cc	120 cc
15" Hg	262 cc	194 cc	43 cc
20" Hg	170 cc	111 cc	Flashing
25" Hg	78 cc	27 cc	Flashing

Table #8: Calculated Residual Gas (headspace volume 550 cc)

As can be seen, higher product temperature reduces the vacuum requirements in order to meet the residual gas requirements. However, care needs to be taken with high product temperatures as product flashing can happen, which means that the products start boiling. Product flashing will result in contaminated seals.

Figure #1: Predicted Residual Gas as function of Product Temperature and Vacuum

Meeting the residual gas level is achievable. However, one needs to realize that as significant high vacuum is required to achieve the target value for production in order to guarantee that 99.9% of the product meets the specification limit. Increasing the specification limit to 250 cc, would increase the target value for residual gas from 100 cc to 175 cc (std=25 cc) or a vacuum level decrease from 24" to 20" Hg. Even lower vacuums can be considered but would require higher fill weights to reduce the headspace volume or higher product fill temperature.

#### 3.6.1.3.2. Closure Seal

The specification for closure seal reads:

*The closure seal, defined as the width of fusion bonded seal at any point perpendicular to the tray flange along the tray perimeter, shall be not less than 1/8 inch wide. The first 1/16 inch of the seal at the food product edge shall be free of defects or anomalies, such as, but not limited to entrapped matter, moisture or grease. The closure seal shall be continuous along the tray flange*

*surface. The closure seal shall be free of impression or design on the seal surface and free of wrinkles.*

Most defects that occurred in the manufacturability studies under this project were anomalies created by moisture and wrinkles caused by the vacuum. Sometimes, a contaminate on the seal plate caused an impression in the seal. Flanges contaminated with pork grease yielded acceptable strength seals with no visual defects. Inadequate seal width defects were resolved by increasing the seal time, but it should be noted that this affects the maximum throughput rate.

Moisture entrapment in the seal was the primary cause for seal defects. The moisture can either be caused by seal contamination before sealing, as was seen in the Pork Sausage in Brine product, or occur by condensation of the headspace gas into the seal as was observed in the hot fill Creamed Ground Beef production run. When moisture is present in the seal, it is incorporated in the molten polypropylene. When the seal pressure is released this incorporated moisture turns to steam and forms tiny bubbles. After the seal cools, the steam condenses and small concave anomalies remain. When the seal time is increased, the molten propylene was moved to the edges of the seal, including the entrapped moisture. The anomalies are still visible along the seal edge, but the remaining seal is free of defects. Stress tests on seals with small anomalies caused by the moisture did not indicate a weakening of the seal. **The US Army Natick Soldier Center has evaluated this anomaly and suggested that the anomaly, caused by moisture, should not be scored as a defect, as long as there is at least 1/8" wide seal. A revised specification is under development. This revised specification would allow for higher line speeds and higher fill temperatures while not sacrificing packaging yield.**

Most seal wrinkles were caused by the vacuum that pulled on the lid material while the seal is still in a semi molten phase. This resulted in movement of the lid and subsequently slight wrinkles in the seal area, primarily in the corners. There are several factors that can either help or aggravate this type wrinkle. To obtain a certain residual gas inside the tray, air needs to be removed from the tray by pulling a vacuum prior to sealing. The amount of vacuum required is determined by the head space volume and the product temperature as was demonstrated in the previous section. Once the vacuum is pulled the lid material is sealed to the tray. When the vacuum is released, the external and internal pressures of the container are equilibrated by reducing the volume of the tray. This happens mainly by drawing the top film into the container. The draw on the film can happen in several ways and depends on the product inside the container. Ideally, the film is gradually drawn into the container with the deepest draw in the center of the container. In this ideal case, the product from the center is moved to the flange area to fill the void. The consistency of the product can however prevent the movement of material. In these cases, the lid material is pulled sharply around the flange into the container, causing wrinkles in primarily the corners.

In case of the Pork Sausage in Brine, the sausages were completely submerged in the brine and the lid material had no problem moving the brine towards the flange to equilibrate the forces. In case of Creamed Ground Beef, the lid material appeared to have more difficulties to move the product and an increase in seal wrinkles was observed at lower fill weights (=more material has to be moved to equilibrate the forces). Tests with a placeble product that was not completely submersed in a liquid, resulted in even more seal wrinkles, because the lid material was not able to move any material toward the flange.

**To avoid seal wrinkles caused by the vacuum, one should ensure that the solids in the tray are submerged in adequate liquid that can be pushed by lid material towards the flange of the tray. This will avoid that the lid is being pulled sharply around the flange and cause wrinkles. Even if the product is submerged in the liquid, seal wrinkles might still occur if the tray has an inadequate fill weight and thus excessive headspace volume which requires a high vacuum and a significant larger pull on the lid to equilibrate the pressures after the vacuum has been released.**

**Increased fill weights is the first line of action that can be taken to prevent seal wrinkles caused by the vacuum release. Preferable the increased fill weight is accomplished by increasing the liquid portion, not the solids portion. Increased fill weight might however become a problem in an indexing vacuum sealer as the product might slosh into the seal area and thus cause contamination. Continuous**

motion sealers such as the one at the CORANET Demo facility had no problems dealing with higher fill weights.

The US Army Natick Soldier Center has evaluated higher residual gas levels and made recommendations to increase the maximum allowable level. This relaxation in specification limit will have a significant effect on the vacuum that needs to be pulled, resulting in an increase of maximum throughput rate and reduction in seal defects caused by vacuum wrinkles.

#### 3.6.1.3.3. Internal Pressure

This specification reads:

*Internal pressure resistance shall be determined by pressurizing the container without protective sleeve while restrained between two rigid plates. There shall be a minimum clearance of 1/8 inch between the bottom surface of the top plate and the top surface of the tray flange (with attached lid). A four-seal tester (designed to pressurize filled container by use of a hypodermic needle through the container wall or lid) shall be used and all four seals tested simultaneously. It may also be necessary to restrain the tray body during the test within either a wood or metal base, such that excessive deflection of the tray does not render a false lid failure.*

*Pressure shall be applied gradually until 20 psig pressure is reached. The 20 psig pressure shall be held constant for 30 seconds and then released. The container then shall be examined for separation or yield of the heat seals. Any rupture of the container or evidence of any seal separation greater than 1/16 inch or seal separation that reduces the closure seal width to less than 1/16 inch shall be considered a test failure.*

The first part of the specification is difficult to implement or to verify due to the nature of a semi flexible container which does not have an exact defined height. Nor is it easy to determine the distance between flange and the top plate during the pressure test.

The test system used in this project consisted out of a Raque Heat Seal carrier with a plate on either side. The tray was therefore supported around the perimeter avoiding stresses in the lid material. The carrier has also a support rim under the flange. The distance from this rim to the top plate was 0.20 inches with rubber gasket and 0.22 inches without rubber gasket which appears to satisfy the specification.

Meeting the internal pressure specification has not been a problem. The seals that were applied were significantly stronger than is required by this specification.

## **Introduction:**

Since the inception of the Tray Pack Ration, the product has been packaged in a heavy metal tray shaped can with a double seamed metal lid and processed in non rotary, batch retort systems. Due to the declining supplier base for the metal tray can and lid and various problems with the interior coating of the cans, an alternative package was developed utilizing a polymeric tray body and a laminated foil and polymer lidstock. The change over to this particular container has a significant impact on the number of containers that can be processed in each retort batch. A larger foot print of the container flange and the requirement that the weight of each container needs to be supported by a racking mechanism rather than by stacking the containers on top of each other reduces the capacity approximately 33%.

The impact of reduction of the batch capacity could be offset if the process cycle time could be reduced by the same amount. This project addresses the main issues involved in heat penetration and the impact of process and product parameters on the required process time.

## **Objective:**

Conduct an experimental designed process study to determine the impact of selected packaging and process variables on the required retort cycle time to yield commercial sterile product.

## **Product and Package Description:**

Pork Sausage Links in Brine is the product that was used in this study and complied with the Contract Technical Requirement dated January 11, 2000 with the exception that the water was used instead of brine.

The sausage links were manufactured by ASE Deli/Foodservice Company, St. Charles, IL. and are the same as used by current producers of "Pork Sausage Links in Brine" for Combat Feed Program. The supplier precooked the sausage links in order to avoid excessive weight loss during the retort process and each weighs approximately 20 grams before retorting and 17 grams after retorting. The sausage dimensions are approximately 3 " long and 1/2 to 3/4" in diameter. Each tray was filled with 72 sausage links, which were placed in two layers, each layer containing three rows of 12 sausages.

The trays used in this experiment were manufactured by Rexam Containers, Union MO and are identified as "Military Steam Table Tray, Type I". The tray weighs approximately 155 grams with a minimal wall thickness of 0.037".

The tray was sealed under vacuum conditions with a Quad laminate film. The film was manufactured by Smurfit Flexible packaging, Shaumburg, IL and is identified as "LC Flex 70466, Green".

### **Process Description:**

The trays were manually filled with sausage links and a thermocouple was placed in the middle of one sausage link, which was placed in the geometric center of the tray. The thermocouples used for the heat penetration study were manufactured by Ecklund-Harrison Technology, Ft. Myers, FL. and are identified as Needle Type thermocouple (4-3/4") type CNL. The tray was placed in the sealing carriers of the Raque Heat Sealer before a pre-weighed amount of water was added to the tray to ensure that the net weight target of 90 oz was met. The tray was sealed at a speed of approximately 8 trays/min. while seal conditions were maintained at 412 F for 2.0 seconds. The vacuum condition was a variable in this study and was controlled by a vacuum timer that opened a vacuum valve for a preset duration. A vacuum time of 1.0 second resulted in an approximate vacuum of 20" Hg in the sealing chamber, yielding trays that had a pre-retort residual gas level of less than 175 cc. A vacuum time of 0.2 seconds resulted in an approximate vacuum of 10" Hg in the sealing chamber, yielding trays that had a pre-retort residual gas level of approximately 350 cc.

Twelve sealed trays with thermocouples were loaded in the front cage of a Stock 1100, four cage Rotomat, using polymeric tray racks specifically designed for this tray. The trays were placed in layers 4 through 9 (two cans per layer). The remaining rack pockets were filled with ballast trays (trays filled with water). The other three cages of the retort were filled with ballast boxes. The polymeric tray racks used in this study were manufactured by Stock America, Grafton, WI and are identified as "7333A". The design features of this rack allowed the trays to be loaded either "face up" or "face down", and the trays are locked into the pocket so that they can be rotated during the retort process without creating abrasion defects. Four retort programs were developed and used in this study. Two programs were designed for a static process. Program #20 processed the tray "up-side-down". Program #21 processed the tray "side ways" to enhance the water flow between the containers (water flow is from top to

bottom in this type retort). Two other programs were designed for a rotational process. Program #22 rotated the tray at a speed of 5 rpm while Program #23 rotated the trays at a speed of 15 rpm. All retort programs used the same temperature and pressure profile. The temperature of the retort was set at 254 F during the Come-Up Phase (S2) and at 252 F during the Hold Phase (S3). Copies of the retort programs can be found in the Appendix I.

The heat penetration data was collected during the process via a system supplied by Ellab Inc, Copenhagen DN. The main components of the system were a 16-channel slip ring assembly, a Analog/Digital converter (CMC) and Ellab CMC software, which had the ability to calculate the  $F_0$  values on-line. The data was analyzed using Ellab's "Eval Basic" software, version 1.20.

The heating phase of the retort process was terminated after all thermocouples had reached an  $F_0$  value of greater or equal to 6.0 min. The cooling phase was terminated after all thermocouples indicated a temperature lower or equal to 120 F.

### **Full Factorial Experimental Design:**

A full factorial design was adopted to investigate the effect of vacuum applied during sealing, rotation speed or retort position. Post Retort Residual Gas and the required Cooking Time (CT) of the product were measured/calculated as response variables.

#### **Static Mode:**

Parameters	Levels		Response
Retort position	Horizontal (Program 20)	Vertical (Program 21)	Residual Gas & CT (Cook Time)
Vacuum applied	20" (targeting 150 cc residual gas)	10" (targeting 350 cc residual gas)	

#### **Rotational Mode:**

Parameters	Levels		Response
Rotation speed, rpm	5 (Program 22)	15 (Program 23)	Residual Gas & CT (Cook Time)
Vacuum applied	20" (targeting 150 cc residual gas)	10" (targeting 350 cc residual gas)	

The total number of experiments required to determine the main effects and interactions for the above two factors was 4 ( $=2^2$ ) for each mode. Each experiment would contain 12 trays with thermocouples and each experiment would be repeated at least once.

### **Data Analysis**

Each tray was analyzed for post-retort residual gas level. This measurement was performed by opening the tray below water and capturing the "free air" in an inverted graduate cylinder. This post-retort residual gas data was the used for statistical analysis.

Using Ball's heat penetration assumptions, each thermocouple lead data was analyzed for the typical heating factors <sup>1</sup> such as  $j_h$ ,  $f_h$ ,  $x_{bh}$ ,  $f_2$ . These heating factors were then used to calculate the required Cook Time to reach a Lethality of  $F_0= 6.0$  min, using a Retort Temperature of 250 F and an Initial Product Temperature of 40 F. The Cook Time variable was then used for statistical analysis. The analysis was divided according to the retort operating modes (Static and Rotational Mode). All statistical analysis was based on the outputs from SAS software, SAS Institute Inc. and / or STATGRAPHICS Plus 5.0, Statistical Graphics Corp. The procedures used in the analysis were General Linear Model (GLM), Multifactor ANOVA, and the Univariate procedures.

### **Refinement of Data:**

The analysis procedure started by refining the raw data by removing the outliers through a two-stage refinement process. The first stage removed the outliers based on the Residual Gas Model.

Observations with absolute standardized residual values (based on Residual Gas model) greater than 2 were removed from the data file.

**Note:** Outliers due to residual gas might have been caused by variation during the sealing process, either due to a sticking valve or a leaking seal chamber. It was deemed prudent to

remove these outliers in order to minimize the impact of excessive variation in residual gas on subsequent analysis.

During the second stage, removing outliers based on the Cook Time model further refined the output from the first stage. The same criteria was used to discard observation with absolute standardized residual values (based on the Cook Time model) greater than 2.

**Note:** The exact location of the thermocouple within the sausage can have a significant effect on the heat penetration rate. Outliers in the Cook Time model might have been caused by shifting of the product during packaging and retort loading, causing an improperly located thermocouple. It was deemed prudent to remove these outliers in order to minimize the impact of incorrect located thermo couples.

The refined data was then used for subsequent analysis of variance and is reported in the following section. The analysis for the two retort modes (static and rotation) will be discussed separately.

**Note:** It should be noted that none of the conclusions reached in the analysis would have been reversed if the outliers had not been removed

### **Static Mode**

### **Residual Gas Analysis:**

The data was first analyzed for post retort Residual Gas level by using a multifactor ANOVA analysis. Summary data, obtained from the SAS output can be found in Appendix-II. Based on this data we can conclude that:

- The overall F-test was significant at 99% confidence level, indicating that the model as a whole accounts for a significant portion of variability in the response variable (Residual Gas).
- The F-test for Program and Vacuum was also significant at 99% confidence level, indicating the means for the different programs and vacuums are not equal.
- The interaction between Program and Vacuum was not significant.

Multiple comparison test (Tukey Test) was used to compare between two retort position and residual gas. The test indicated, as expected, that the vacuum applied during sealing had a significant impact on the residual gas level inside the tray after retorting. However, the test also indicated (at 0.05 significance level) that the post retort Residual Gas value is significantly effected by the retort position. The residual gas level was significantly higher when the product was processed in a vertical position retort position (C) , (Program 21). Because the trays were filled and sealed in a random manor, it is assumed that there would have been no significant difference between pre-retort residual gas levels inside the tray under the same vacuum conditions. It is therefore hypothesized that less air is "consumed" by, or more air expelled from the product during a vertical retort process when more product is immersed in the brine and less product is exposed the "headspace" inside the can.

Tukey Grouping	Mean	N	Program
A	276.7	67	21
B	231.1	50	20

\*Means with the same letter are not significantly different.

Tukey Grouping	Mean	N	Vacuum
A	375.3	50	10"

21	10"	33		380.5	26.8	0.07

Interaction Plot

### Cook Time Analysis:

The refined data was then analyzed for Cook Time using a multifactor ANOVA analysis. Summary data, obtained from the SAS output can be found in Appendix-II. Based on this data we can conclude that:

- The overall F-test was significant at 99% confidence level, indicating that the model as a whole accounts for a significant portion of variability in the response variable (Cooking Time).
- The F-test for Program and Vacuum were also significant at 99% confidence level, indicating the means for the different programs and vacuums are not equal.
- The interaction between Program and Vacuum was not significant.

Multiple comparison test (Tukey Test) was used to compare between the different levels of retort position and residual gas. The output from the test (at 0.05 significance level) indicated that we have a lower CT value (faster heating) when the tray was processed vertical in the retort, (Program 21), and/or sealed under a 20" vacuum (~150 cc).

Tukey Grouping	Mean	N	Program
A	32.10	50	20
B	26.28	67	21

\*Means with the same letter are not significantly different.

Tukey Grouping	Mean	N	Vacuum
A	29.57	50	10"
B	28.17	67	20"

\*Means with the same letter are not significantly different.

The data was then analyzed for the mean value per treatment (combination of program and vacuum). As one can see from the table below and from the accompanying graph that program 20 with a low vacuum level results in the longest Cook Time while program 21 (vertical) with a high vacuum level results in the shortest Cook Time. The hypothesis is that the vertical process enhances the water flow between the containers and improves the heat transfer rate from the heating media into the container. This increased external heat transfer is especially important for fast heating products such as Pork Sausage Links in Brine, but might be less significant in slow heating products where the overall heat transfer rate is determined by the internal heat transfer rate of the tray.

### **Means Analysis per Treatment:**

Level Of Program	Level Of Vacuum	N	CT			
			R-Square CV	Mean	SD	CV
20	20"	33	0.78	31.21	1.64	0.053
20	10"	17	0.058	33.85	2.11	0.062
21	20"	34		25.23	1.38	0.055
21	10"	33		27.36	1.74	0.063

### **Model Assessment:**

The R-Square value=0.78 in the ANOVA Table is evidence of a good fit is provided by the model. This value indicates that 78% of the variability in CT can be explained when retort position and residual gas are used as independent variables.

### **Assessing Normality:**

The large value of 0.9665 for Shapiro-Wilk test and Normal Probability Plot all support the assumption of normality. This means that it is appropriate to use ANOVA analysis.

### Accessing of Equality of Variance:

The Plot of Studentized Residual \* Predicted CT shows a plot of residuals vs. predicted values of CT . Based on this plot, there is no strong evidence for unequal variances and for outliers. This means that our methodology for refining the data was successful.

### Location of Tray Analysis:

Multiple Range Tests for Cook Time by Location (Appendix-II) revealed no statistically significant differences between any pair of means at the 95.0% confidence level. The method used to discriminate among the means is Tukey's honestly significant difference (HSD) procedure.

## **Dynamic Mode:**

### **Residual Gas Analysis:**

The data was first analyzed for post retort Residual Gas level by using a multifactor ANOVA analysis. Summary data, obtained from the SAS output can be found in Appendix-III. Based on this data we can conclude that:

- The overall F-test was significant at 99% confidence level, indicating that the model as a whole accounts for a significant portion of variability in the response variable (Residual Gas).
- The F-test for Program and Vacuum was also significant at 99% confidence level, indicating the means for the different programs and vacuums are not equal.
- The interaction between Program and Vacuum was significant at 99% confidence.

Multiple comparison test (Tukey Test) was used to compare between the two retort rotational speeds and residual gas. The test indicated, as expected, that the vacuum applied during sealing had a significant impact on the residual gas level inside the tray after retorting. However, the test also indicated (at 0.05 significance level) that the post retort Residual Gas value was significantly affected by the retort rotational speed. The residual gas level was significantly higher when the product was processed at rotational speed of 5 rpm , (Program 22). Because the trays were filled and sealed in a random manor, it can be assumed that there would be no significant difference between pre-retort residual gas levels inside the tray when the same vacuum condition was used. It is therefore hypothesized that less air is "consumed", or more air expelled by the product during a slow rotational retort process (5 rpm).

Tukey Grouping	Mean	N	Program
A	224.4	42	22
B	185.0	53	23

\*Means with the same letter are not significantly different.

Tukey Grouping	Mean	N	Vacuum
A	284.3	40	10"
B	142.9	55	20"

\*Means with the same letter are not significantly different.

### Means Analysis per Treatment:

Retort Program	Level Of Vacuum	N	Residual Gas			
			R-Square CV	Mean	SD	CV
22	20"	24	0.942 0.090	157.9	15.9	0.10
22	10"	18		313.1	28.0	0.089
23	20"	31		131.3	14.5	0.11
23	10"	22		260.8	15.1	0.058

Interaction Plot

### Cook Time Analysis:

The refined data was then analyzed for Cook Time using a multifactor ANOVA analysis. Summary data, obtained from the SAS output can be found in Appendix-III. Based on this data we can conclude that:

- The overall F-test was significant at 99% confidence level, indicating that the model as a whole accounts for a significant portion of variability in the response variable (Cooking Time).
- The F-test for Program and Vacuum are also significant at 99% confidence level, indicating the means for the different programs and vacuums are not equal.
- The interaction between Program and Vacuum is significant at 95% confidence.

Multiple comparison test (Tukey Test) was used to compare between the different levels of rotational speed and residual gas. The output from the test (at 0.05 significance level) indicated that we have a

lower CT value (faster heating) when the tray was processed at a rotational speed of 15 rpm, (Program 23), and/or sealed under a 20" vacuum (~ 150cc).

Tukey Grouping	Mean	N	Program
A	29.32	42	22
B	24.70	53	23

\*Means with the same letter are not significantly different.

Tukey Grouping	Mean	N	Vacuum
A	27.66	40	10"
B	26.07	55	20"

\*Means with the same letter are not significantly different.

The data was then analyzed for the mean value per treatment (combination of program and vacuum). Program 22 with a low vacuum level (10" and ~350 cc res. gas) resulted in the longer Cook Time, while program 23 (15 rpm) with a high vacuum level (20" and 150 cc res. gas) resulted in the shortest Cook Time. This negative impact of higher levels of residual gas on heating rate was unexpected. Typically, higher residual gas levels assist in the flow of material inside the tray. It is hypothesized that the overall heat transfer is determined by the external heat transfer into the container and the natural convective flow of the brine is sufficient in transferring the heat throughout the tray. Forced convective flows inside the tray due to the rotation have no benefits in enhancing heat transfer in this particular type product. In fact, it is hypothesized that the additional air inside the tray appears to actually slow down the heat transfer from the container walls into the product.

### Means Analysis per Treatment:

Level Of Program	Level Of Vacuum	N	CT			
			R-Square CV	Mean	SD	CV
22	150	24	0.64 0.070	29.07	1.34	0.046
22	350	18		29.65	1.76	0.059
23	150	31		23.75	2.06	0.087
23	350	22		26.03	2.18	0.084

Interaction Plot

### Location of Tray Analysis:

Multiple Range Tests for Cook Time by Location (Appendix-III) revealed no statistically significant differences between any pair of means at the 95.0% confidence level. The method used to discriminate among the means is Tukey's honestly significant difference (HSD) procedure.

### Model Assessment:

#### **The fit of the model:**

Evidence of a good fit is provided by the R-Square value= 0. 64. Nearly 64% of the variability in CT has been explained when rotational speed and residual gas are used as independent variables.

#### **Assessing Normality:**

The large value of 0.960 for Shapiro-Wilk test and Normal Probability Plot all support an assumption of normality.

Normal Probability Plot

**Accessing of Equality of Variance:**

The Plot of Studentized Residual \* Predicted CT shows a plot of residuals vs. predicted values of CT. Based on this plot, there is no strong evidence for unequal variances and for outliers.

Residual Plot

## **Conclusions:**

The statistical results (based on the full factorial baseline experiments) indicate that:

- ❑ Post Retort Residual Gas is affected by the retort process
- ❑ Location of the tray within the crate seems to be not significant, indicating good heating uniformity throughout the crate and no serious cold spots in any of the four programs.
- ❑ The calculated cook time based on the heating factors is significantly impacted by the vacuum condition/residual gas inside the tray and by the retort position/speed.
- ❑ The slowest packaging/retort condition is a low vacuum pack (10") processed in static horizontal position.
- ❑ The fastest packaging/retort condition is a high vacuum pack (20"), processed in a high-speed rotational process (15 rpm).
- ❑ Outliers have no effect on the above conclusions.

## 1. RESIDUAL GAS ANALYSIS

### **a.1 Probability Plot - Residual G (Vacuum=10 & first(117))**

#### **Analysis Summary**

Data variable: Residual G

Selection variable: Vacuum=10 & first(117)

50 values ranging from 315.0 to 430.0

### **a.2 Probability Plot - Residual G (Vacuum=20 & first(117))**

#### **Analysis Summary**

Data variable: Residual G

Selection variable: Vacuum=20 & first(117)

67 values ranging from 108.0 to 210.0

## b. Multifactor ANOVA - Residual G (first (117))

### Analysis Summary

Dependent variable: Residual G

Factors:

Program

Vacuum

Selection variable: first (117)

Number of complete cases: 117

### Analysis of Variance

Source	Sum of Squares	Df	Mean Square	F-Ratio	P-Value
Model	1.22308E6	3	407694.0	678.36	0.0000
Residual	67912.6	113	600.996		
Total (Corr.)	1.29099E6	116			

R-squared = 94.7395 percent

R-squared (adjusted for d.f.) = 94.5999 percent

Standard Error of Est. = 24.5152

Mean absolute error = 20.5006

Durbin-Watson statistic = 1.69605 (P=0.0502)

Lag 1 residual autocorrelation = 0.145914

### Analysis of Variance for Residual G - Type III Sums of Squares

Source	Sum of Squares	Df	Mean Square	F-Ratio	P-Value
MAIN EFFECTS					
A:Program	5747.98	1	5747.98	9.56	0.0025
B:Vacuum	1.11687E6	1	1.11687E6	1858.36	0.0000
INTERACTIONS					
AB	7.7108	1	7.7108	0.01	0.9100
RESIDUAL	67912.6	113	600.996		
TOTAL (CORRECTED)	1.29099E6	116			

All F-ratios are based on the residual mean square error.

Scatterplot by Level Code

Means and 95.0 Percent Tukey HSD Intervals

Interaction Plot

Residual Plot for Residual G

## **2. COOK TIME ANALYSIS**

### **a. Probability Plot - CT (first (117))**

#### **Analysis Summary**

Data variable: CT

Selection variable: first (117)

117 values ranging from 21.83 to 36.99

### **b. Multifactor ANOVA - CT (first (117))**

#### **Analysis Summary**

Dependent variable: CT

Factors:

Program

Vacuum

Selection variable: first (117)

Number of complete cases: 117

#### **Analysis of Variance**

Source	Sum of Squares	Df	Mean Square	F-Ratio	P-Value
Model	1126.81	3	375.605	134.05	0.0000
Residual	316.62	113	2.80195		
<hr/>					
Total (Corr.)	1443.44	116			

R-squared = 78.0648 percent

R-squared (adjusted for d.f.) = 77.4825 percent

Standard Error of Est. = 1.6739

Mean absolute error = 1.34034

Durbin-Watson statistic = 1.55459 (P=0.0077)

Lag 1 residual auto correlation = 0.212667

# Analysis of Variance for CT - Type III Sums of Squares

Source	Sum of Squares	Df	Mean Square	F-Ratio	P-Value
MAIN EFFECTS					
A:Program	1044.48	1	1044.48	372.77	0.0000

# **1 Introduction**

Since the inception of the Tray Pack Ration, the product has been packaged in a heavy metal tray shaped can with a double seamed metal lid and processed in non rotary, batch retort systems. Due to the declining supplier base for the metal tray can and lid and various problems with the interior coating of the cans, an alternative package was developed utilizing a polymeric tray body with a laminated foil and polymer lidstock. The change over to this particular container has a significant impact on the number of containers that can be processed in each retort batch. A larger foot print of the container flange and the requirement that the weight of each container needs to be supported by a racking mechanism rather than by stacking the containers on top of each other reduces the capacity approximately 33%.

The reduction in batch capacity can be offset, if the process cycle time can be reduced by the same percentage. This project investigates the impact of selected process and product parameters on the heat penetration rate of the product and the required process time to render the product commercial sterile.

## **2 Objective**

Conduct an experimental designed process study to determine the impact of selected packaging and process variables on the required retort cycle time to yield commercial sterile product.

### **3 Product and Package Description**

Creamed Ground Beef, the product that was used in this study, complies with the Contract Technical Requirement dated January 11, 2000.

The precooked ground beef used for this study was manufactured by St James Gourmet, Farmingdale NY. The ground beef was partial precooked, frozen and packed in cryovac bags by the supplier for easier handling. The ground beef was re-blanching at the FMT facility to avoid excessive weight loss during the retort process and thinning of the sauce. Also, the precooking/blanching process removed excessive fat and juices, which otherwise might yield an unacceptable product.

The cream sauce was made according to the recommended formula in the product specification with the exception that the starch quantity was reduced from 6% to 5.5%. The three main ingredients: "Starch", "Dry Cream" and "Shortening" were manufactured by respectively National Starch, Bridgewater NJ (Purity W), Quality Ingredients, Burnsville MN (Quali-Cream 7211) and Kerry Inc, Beloit WI (NDX-112 V, Item No. I1529).

The trays used in this experiment were manufactured by Rexam Containers, Union MO and are identified as "Military Steam Table Tray, Type I". The tray weighs approximately 155 grams with a minimal wall thickness of 0.037".

The tray was sealed under vacuum conditions with a Quad laminate film. The film was manufactured by Smurfit Flexible packaging, Schaumburg, IL and is identified as " LC Flex 70466, Green".

## 4 Process Description:

The cream sauce was made in a jacketed kettle, equipped with high speed mixer and scrape surface agitator using the following procedure:

- 1) Mix required quantity of starch in small quantity of cold water and mix vigorously to form a thin slurry.
- 2) Add remaining quantity of cold water to kettle.
- 3) Add Dry Cream to kettle and mix vigorously (speed setting: 2) till all dissolved.
- 4) Add remaining ingredients (except starch slurry) to kettle and mix while heating kettle till product reaches 180 F to 190 F. Use high heat setting
- 5) Add starch slurry and the final mixture should be heated to 180 F to 190 F and held at this temperature for 5 minutes. (Use low heat setting once 180 F is reached)
- 6) If product needs to be refrigerated, cool product to 90 F and pump into buckets. Label buckets with material ID and Lot Number. Place product in refrigerator.

After the precooked ground beef was blanched at out facility to remove excessive fat and juices from the ground beef, the ground beef was drained and mixed with the refrigerated cream sauce at a ration of 32 oz of ground beef to 60 oz of cream sauce.

The trays were filled to a net weight of 92 oz. The trays intended for heat penetration studies were equipped with a thermocouple that was placed in the middle of the tray and held in place by a 1.5" diameter spacer disk which was placed near the end of the thermocouple. The thermocouples used for the heat penetration study were manufactured by Ecklund-Harrison technology, Ft. Myers FL. and are identified as Needle Type thermocouple (4-3/4") type CNL.

The filled trays were placed in the sealing carriers of the Raque Heat Sealer and sealed at a speed of approximately 8 trays/min. while seal conditions were maintained at 412 F for 2.0 seconds. The vacuum condition was a variable in this study. and was controlled by a vacuum timer that opened a vacuum valve for a preset duration. A vacuum time of 1.0 seconds resulted in an approximate vacuum of 20" Hg in the sealing chamber, yielding trays that had a pre-retort residual gas level of less then 175 cc. A vacuum time of 0.17 seconds resulted in an approximate vacuum of 10" Hg in the sealing chamber, yielding trays that had a pre-retort residual gas level of approximately 350 cc.

Twelve sealed trays with thermocouples were loaded "face up" in the front cage of a Stock 1100, four cage Rotomat, using polymeric tray racks specifically designed for this tray. The trays were placed in layers 4 through 9 (two cans per layer). Several additional trays without thermocouples were also placed within these layers and retorted to yield samples for post process product evaluation. All remaining rack pockets were filled with ballast trays (trays filled with water). The other three cages of the retort were filled with ballast boxes. The polymeric tray racks used in this study were manufactured by Stock America, Grafton, WI and are identified as "7333A". The design features of this rack allowed the trays to be loaded either "face up" or "face down", and the tray are locked into the pocket so that they can be rotated during the retort process without creating abrasion defects.

Four retort programs were developed and used in this study. Two programs were designed for a static process. Program #20 processed the tray "up-side-down". Program #21 processed the tray "side ways" to enhance the water flow between the containers (water flow is from top to bottom in this type retort). Two other programs were designed for a rotational process. Program #22 rotated the tray at a speed of 5 rpm while Program #23 rotated the trays at a speed of 15 rpm. All retort programs used the same temperature and pressure profile. The temperature of the retort was set at 254 F during the Come Up Phase (S2) and at 252 F during the Hold Phase (S3). Copies of the retort programs can be found in the Appendix I.

The heat penetration data was collected during the process via a system supplied by Ellab Inc, Copenhagen DN. The main components of the system were a 16 channel slip ring assembly, a Analog/Digital converter (CMC) and Ellab CMC software, which had the ability to calculate the  $F_0$  values on-line. The data was analyzed using Ellab's "Eval Basic" software, version 1.20.

The heating phase of the retort process was terminated after all thermocouples had reached an  $F_0$  value of greater or equal to 6.0 min. The cooling phase was terminated after all thermocouples indicated a temperature lower or equal to 120 F.

## 5 Full Factorial Experimental Design:

A full factorial design was adopted to investigate the effect of vacuum applied during sealing and retort rotation speed or crate position. Post Retort Residual Gas, Post Retort Product Consistency and the required Cooking Time (CT) of the product were measured/calculated as response variables. The analysis was divided according to the retort operating modes (Static and Dynamic Mode).

### Static Mode:

Parameters	Levels		Response
Retort position	Horizontal (Program 20)	Vertical (Program 21)	Residual Gas, Product Consistency & CT (Cook Time)
Vacuum applied	20" (targeting 150 cc residual gas)	10" (targeting 350 cc residual gas)	

### Dynamic Mode:

Parameters	Levels		Response
Rotation speed, rpm	5 (Program 22)	15 (Program 23)	Residual Gas, Product Consistency & CT (Cook Time)
Vacuum applied	20" (targeting 150 cc residual gas)	10" (targeting 350 cc residual gas)	

The total number of experiments required to determine the main effects and interactions for the above two factors was 4 ( $=2^2$ ) for each mode. Each experiment would contain 12 trays with thermocouples and a few additional trays without thermocouples. Each experiment would be repeated at least once.

## 6 Data Analysis

Using Ball's heat penetration assumptions, each thermocouple lead data was analyzed for the typical heating factors<sup>1</sup> such as  $jh$ ,  $fh$ ,  $xbh$ ,  $f_2$ . These heating factors were then used to calculate the required Cook Time to reach a Lethality of  $F_0 = 6.0$  min, using a Retort Temperature of 250 F and an Initial Product Temperature of 80 F. The Cook Time variable was then used for statistical analysis. The analysis was divided according to the retort operating modes (Static and Rotational Mode).

Each tray with a thermocouples was also analyzed for post-retort residual gas level. This measurement was performed by opening the tray below water and capturing the "free air" in an inverted graduate cylinder. This post-retort residual gas data was the used for statistical analysis.

One of the trays without thermocouple was analyzed for product consistency. This measurement was done by heating the product, draining the sauce from the ground beef in a #7 sieve and measuring the consistency in a Bostwick Consistometer. Due to the limited data, data is reported "as is" and no statistical analysis could be performed.

All statistical analysis was based on the outputs from SAS software<sup>4</sup>, SAS Institute Inc and StatGraphics version 5.0<sup>5</sup>. The statistical procedures used in the analysis were General Linear Model (GLM), Multifactor ANOVA, and the Univariate procedures.

### 6.1 Refinement of Data

The analysis procedure started by refining the raw data by removing the outliers through two-stage refinement process. The first stage removed the outliers based on residual gas model. Observations with absolute standardized residual values (based on Residual Gas model) greater than 2 were removed from the data file.

**Note:** Outliers due to residual gas might have been caused by variation during the sealing process, either due to a sticking valve or a leaking seal chamber. It was deemed prudent to remove these outliers in order to minimize the impact of excessive variation in residual gas on subsequent analysis.

During the second stage, removing outliers based on the Cook Time model further refined the output from the first stage. The same criteria was used to discard observation with absolute standardized residual values (based on the Cook Time model) greater than 2.

**Note:** The exact location of the thermocouple within container can have a significant effect on the heat penetration rate. Outliers in the Cook Time model might have been caused by shifting of spacer disk during packaging and retort loading, causing an improperly located thermocouple. It was deemed prudent to remove these outliers in order to minimize the impact of incorrect located thermocouples.

The refined data was then used for subsequent analysis of variance and is reported in the following section. The analysis for the two retort modes (static and rotation) will be discussed separately.

**Note:** It should be noted that none of the conclusions reached in the analysis would have been reversed if the outliers would not have been removed.

## 6.2 Static Mode

### 6.2.1 Residual Gas Analysis:

The data was first analyzed for post retort Residual Gas level by using a multifactor ANOVA analysis. Summary data, obtained from the SAS output can be found in Appendix-II. Based on this data we can conclude that:

- The overall F-test was significant at 99% confidence level, indicating that the model as a whole accounts for a significant portion of variability in the response variable (Residual Gas).
- The F-test for Program and Vacuum was also significant at 99% confidence level, indicating the means for the different programs and vacuums are not equal.
- The interaction between Program and Vacuum was significant at 95% confidence level.

Multiple comparison test (Tukey Test) was used to compare between the two retort positions and the two levels of vacuum. The test indicated, as expected, that the vacuum applied during sealing had a significant impact on the residual gas level inside the tray after retorting. However, the test also indicated (at 0.05 significance level) that the post retort Residual Gas value was significantly affected by the retort position. The residual gas level was significantly higher when the product was processed in a vertical position, retort position (C) - (Program 21). Because the trays were filled and sealed in a random manor, it can be assumed that there would have been no significant difference between pre-retort residual gas levels inside the tray under the same vacuum conditions. It is therefore hypothesized that less air is "consumed" by, or more air expelled from the product during a vertical retort process when less product is exposed to the "headspace" inside the can.

Tukey Grouping	Mean	N	Program
A	244.3	44	21
B	199.3	42	20

\*Means with the same letter are not significantly different.

Tukey Grouping	Mean	N	Vacuum
A	341.5	39	10"
B	123.4	47	20"

\*Means with the same letter are not significantly different.

### Means Analysis per Treatment:

Retort Program	Level of Vacuum	N	Residual Gas			
			R-Square CV	Mean	SD	CV
20	20"	24	0.969 0.089	111	14	0.13
20	10"	18		316.9	23.6	0.07
21	20"	23		136.3	17.4	0.13
21	10"	21		362.6	24.4	0.07

Interaction Plot

### 6.2.2 Cook Time Analysis

The refined data was then analyzed for Cook Time using a multifactor ANOVA analysis. Summary data, obtained from the SAS output can be found in Appendix-II. Based on this data we can conclude that:

- The overall F-test was significant at 99% confidence level, indicating that the model as a whole accounts for a significant portion of variability in the response variable (Cooking Time).
- No significant difference between the means of programs 20 and 21.
- The F-test for Vacuum was significant at 99% confidence level, indicating the means at the different vacuum levels are not equal.
- The interaction between Program and Vacuum was significant at 99% confidence level.

Multiple comparison test (Tukey Test) was used to compare between the different levels of vacuum. The output from the test (at 0.05 significance level) indicated that we have a lower CT value (faster heating) when the tray was processed sealed under a 20" vacuum (~150 cc).

Tukey Grouping	Mean	N	Vacuum
A	88	39	10"
B	74.7	47	20"

\*Means with the same letter are not significantly different.

The data was then analyzed for the mean value per treatment (combination of program and vacuum). As one can see from the table below and from the accompanying graph that program 21 with a low vacuum level (10") results in the longest Cook Time while program 21 (vertical) with a high vacuum level (20") results in the shortest Cook Time.

#### **Means Analysis per Treatment:**

Level Of Program	Level Of Vacuum	N	CT			
			R-Square CV	Mean	SD	CV
20	20"	24	0.92 0.026	75.79	1.90	0.025
20	10"	18		86.6	2.77	0.031
21	20"	23		73.66	1.99	0.027
21	10"	21		89.35	1.61	0.018

**Model Assessment:**

The R-Square value=0.92 in the ANOVA Table is evidence of a good fit is provided by the model. This value indicates that 92% of the variability in CT can be explained when retort position and vacuum level are used as independent variables.

**Assessing Normality:**

The large value of 0.87 for Shapiro-Wilk test and Normal Probability Plot all support the assumption of normality. This means that it is appropriate to use ANOVA analysis.

#### Accessing of Equality of Variance:

The Plot of Studentized Residual \* Predicted CT shows a plot of residuals vs. predicted values of CT. Based on this plot, there is no strong evidence for unequal variances and for outliers. This means that our methodology for refining the data was successful.

### 6.2.3 Location of Tray Analysis:

Multiple Range Tests for Cook Time by Location within the retort crate (Appendix-II) revealed no statistically significant differences between any pair of means at the 95.0% confidence level. The method used to discriminate among the means is Tukey's honestly significant difference (HSD) procedure.

### 6.3 Dynamic Mode:

#### 6.3.1 Residual Gas Analysis:

The data was first analyzed for post retort Residual Gas level by using a multifactor ANOVA analysis. Summary data, obtained from the SAS output can be found in Appendix-III. Based on this data we can conclude that:

- The overall F-test was significant at 99% confidence level, indicating that the model as a whole accounts for a significant portion of variability in the response variable (Residual Gas).
- The F-test for Program was not significant at 95% confidence level.
- The F-test for Vacuum was significant at 99% confidence level, indicating the means for the different vacuums are not equal.
- The interaction between Program and Vacuum was not significant at 95% confidence level.

Multiple comparison test (Tukey Test) was used to compare between the different levels of vacuum. The test indicated, as expected, that the vacuum applied during sealing had a significant impact on the residual gas level inside the tray after retorting.

Tukey Grouping	Mean	N	Vacuum
A	275.7	46	10"
B	100	53	20"

\*Means with the same letter are not significantly different.

#### Means Analysis per Treatment:

Retort Program	Level Of Vacuum	N	Residual Gas			
			R-Square CV	Mean	SD	CV
22	20"	22	0.973 0.081	97	11	0.11
22	10"	23		278	16.97	0.06
23	20"	31		102.2	13.95	0.14
23	10"	23		273.5	16.26	0.06

### 6.3.2 Cook Time Analysis:

The refined data was then analyzed for Cook Time using a multifactor ANOVA analysis. Summary data, obtained from the SAS output can be found in Appendix-III. Based on this data we can conclude that:

- The overall F-test was significant at 99% confidence level, indicating that the model as a whole accounts for a significant portion of variability in the response variable (Cooking Time).
- The F-test for Program and Vacuum were also significant at 99% confidence level, indicating the means for the different programs and vacuums are not equal.
- The interaction between Program and Vacuum was significant at 95% confidence.

Multiple comparison test (Tukey Test) was used to compare between the different levels of rotational speed and vacuum. The output from the test (at 0.05 significance level) indicated that we have a lower CT value (faster heating) when the tray was processed at a rotational speed of 15 rpm, (Program 23), and/or sealed under a 10" vacuum (~ 350cc).

Tukey Grouping	Mean	N	Program
A	57.4	45	22
B	49.3	54	23

\*Means with the same letter are not significantly different.

Tukey Grouping	Mean	N	Vacuum
A	57.55	53	20"
B	47.70	46	10"

\*Means with the same letter are not significantly different.

The data was then analyzed for the mean value per treatment (combination of program and vacuum). Program 22 with a high vacuum level (20" and ~150 cc res. gas) resulted in the longer Cook Time, while program 23 (15 rpm) with a low vacuum level (10" and 350 cc res. gas) resulted in the shortest Cook Time.

This positive impact of higher levels of residual gas on heating rate is well documented by many researchers in this type product. The "gas bubble" moves through the sauce while the tray is rotated, causing the sauce to flow. The so-called "forced convective flows" inside the tray due to the moving gas bubble enhances the heat transfer rate inside the tray.

**Note:** It should be pointed out that this phenomena could not be substantiated in a fast heating product such as "Pork Sausage Links in Brine" (TWP213) <sup>6</sup>, where the heat transfer rate seemed to be limited by the external heat transfer rate. It might also not occur in very viscous products such as "Mashed Potatoes" when the gas bubble is not able to move through the product.

### Means Analysis per Treatment:

Level Of Program	Level Of Vacuum	N	CT			
			R-Square CV	Mean	SD	CV
22	20"	22	0.86 0.05	63.59	3.01	0.047
22	10"	23		51.49	2.53	0.049
23	20"	31		53.26	2.59	0.048
23	10"	23		43.92	2.66	0.06

Interaction Plot

### Model Assessment:

#### **The fit of the model:**

Evidence of a good fit is provided by the R-Square value= 0. 86. Nearly 86% of the variability in CT has been explained when rotational speed and vacuum level are used as independent variables.

#### **Assessing Normality:**

The large value of 0.97 for Shapiro-Wilk test and Normal Probability Plot all support an assumption of normality.

Normal Probability Plot

**Accessing of Equality of Variance:**

The Plot of Studentized Residual \* Predicted CT shows a plot of residuals vs. predicted values of CT. Based on this plot, there is no strong evidence for unequal variances and for outliers. This means that our methodology for refining the data was successful.

Residual Plot

### 6.3.3 Location of Tray Analysis:

Multiple Range Tests for Cook Time by Location (Appendix-III) revealed no statistically significant differences between any pair of means at the 95.0% confidence level. The method used to discriminate among the means is Tukey's honestly significant difference (HSD) procedure.

## **6.4 Comparisons of Static and Dynamic Retort Processing**

### **6.4.1 Residual Gas**

It was concluded that there was no significant impact of the program mode (program 22 and 23) on the post retort residual gas. However, there was a very significant reduction in post retort residual gas level when one switches from static (program 20/21) to dynamic (program 22/23) retort processing. It is hypothesized that less air is "consumed" by, or more air expelled from the product during a static retort process when less product is exposed to the "headspace" inside the can.

Program	Vacuum [inches Hg]	Post Process Residual Gas [cc]
Static	10	341.5
	20	123.4
Dynamic	10	275.7
	20	100.0

### **6.4.2 Product Color**

The sauce color darkened significantly during rotational retort processing. However, samples submitted to The US Army Natick Soldier Center, Group Ration Team at Natick were still rated as "acceptable". The darkening of the sauce color can be compensated by using "titanium di-oxide" in the sauce formulation

#### 6.4.3 Product Consistency Data

Rotational retort processing had a significant impact on the consistency of the product after retorting as can be seen in the table below. Consistency is measured by the distance the sauce travels during a 10 second time frame. Therefore rotational retort process leads to a thinner sauce. Samples submitted to The US Army Natick Soldier Center, Group Ration Team at Natick were rated as "acceptable"

Program	Vacuum [inches Hg]	Consistency [cm/10 sec]
20	10	4.3
	20	4.4
21	10	4.2
	20	4.7
22	10	7.3
	20	6.7
23	10	6.4
	20	7.1

## 7 Conclusions

- ❑ Post retort residual gas is affected by the retort process. The effects were seen between the two static modes and between static and dynamic process. No significant effects were seen between 5 rpm and 15 rpm.
- ❑ Location of the tray within the retort crate was not significant, indicating good heating uniformity throughout the crate and no serious cold spots in any of the four programs.
- ❑ The calculated cook time based on the heating factors is significantly impacted by the vacuum condition/residual gas inside the tray and by the retort position or speed
- ❑ The slowest Cook Time was observed when the product was packed off under 10 inches of vacuum and processed in a vertical position
- ❑ The fastest Cook Time was observed when the product was packed off under 10 inches of vacuum and processed in a rotational retort process at 15 rpm.
- ❑ Outliers that were removed from the data would have no effect on the above conclusions if they would not have been removed.

## 1. RESIDUAL GAS ANALYSIS

### **a.1 Probability Plot - Residual G (Vacuum=10 & first(86))**

#### **Analysis Summary**

Data variable: Residual G

39 values ranging from 270.0 to 405.0

Normal Probability Plot

### **a.2 Probability Plot - Residual G (Vacuum=20 & first(86))**

#### **Analysis Summary**

Data variable: Residual G

47 values ranging from 88.0 to 182.0

Normal Probability Plot

## b. Multifactor ANOVA - Residual G (first (86))

### Analysis Summary

Dependent variable: Residual G

Factors:

Program

Vacuum

Selection variable: first (86)

Number of complete cases: 86

### Analysis of Variance

Source	Sum of Squares	Df	Mean Square	F-Ratio	P-Value
Model	1.04228E6	3	347427.0	874.53	0.0000
Residual	32576.3	82	397.272		
Total (Corr.)	1.07486E6	85			

R-squared = 96.9692 percent

R-squared (adjusted for d.f.) = 96.8584 percent

Standard Error of Est. = 19.9317

Mean absolute error = 15.5674

Durbin-Watson statistic = 1.48637 (P=0.0031)

Lag 1 residual autocorrelation = 0.245568

### Analysis of Variance for Residual G - Type III Sums of Squares

Source	Sum of Squares	Df	Mean Square	F-Ratio	P-Value
MAIN EFFECTS					
A:Program	26719.7	1	26719.7	67.26	0.0000
B:Vacuum	992385.0	1	992385.0	2498.00	0.0000
INTERACTIONS					
AB	2212.84	1	2212.84	5.57	0.0206
RESIDUAL	32576.3	82	397.272		
TOTAL (CORRECTED)	1.07486E6	85			

All F-ratios are based on the residual mean square error.

Scatterplot by Level Code

Means and 95.0 Percent Tukey HSD Intervals

Interaction Plot

Residual Plot for Residual G

## 2. COOK TIME ANALYSIS

### **a. Probability Plot - CT (first (86))**

#### **Analysis Summary**

Data variable: Cook Time

Selection variable: first (86)

86 values ranging from 70.2 to 92.78

### **b. Multifactor ANOVA - CT (first (86))**

#### **Analysis Summary**

Dependent variable: CT

Factors:

Program

Vacuum

Selection variable: first (86)

Number of complete cases: 86

#### **Analysis of Variance**

Source	Sum of Squares	Df	Mean Square	F-Ratio	P-Value
Model	3915.5	3	1305.17	302.40	0.0000
Residual	353.916	82	4.31605		
Total (Corr.)	4269.42	85			

R-squared = 91.7104 percent

R-squared (adjusted for d.f.) = 91.4072 percent

Standard Error of Est. = 2.07751

Mean absolute error = 1.69887

Durbin-Watson statistic = 1.89814 (P=0.2174)

Lag 1 residual autocorrelation = 0.0398343

# **Analysis of Variance for CT - Type III Sums of Squares**

Source	Sum of Squares	Df	Mean Square	F-Ratio	P-Value
MAIN EFFECTS					
A:Program	2.01568	1	2.01568	0.47	0.4963
B:Vacuum	3729.69	1	3729.69	864.15	0.0000

## **Introduction**

Earlier manufacturing studies examined polymeric tray pack production at fixed production rates which were based on semi-commercial rates ranging from 2 to 10 trays/min. The commercial heat sealer at Rutgers routinely processes non-military polymeric trays at 15 trays/min and the heat sealer is rated at 30 trays/min. It is expected that operating rates have a significant impact on production economics but might be limited by specification constraints.

The retort capacity decreases significantly when the industry switches over to the polymeric half steam table tray due to its slightly larger size and the fact that the weight of each container needs to be supported by a racking mechanism rather than stacking the containers on top of each other. A typical Stock 1100 retorts can only process 192 polymeric containers per load versus 288 metal containers. However, if a properly designed rack is used, one might be able to rotate the product during the retort process. The heating rate of some products can be significantly affected by this rotation and be able to at least partially offset the loss in batch size by decreasing the cycle time.

## **Objective**

Perform a production system-analysis including subsystems for filling, sealing and retorting of product in polymeric trays. The analysis output is to include impact of production rates and investments on cost per unit.

## **Modeling**

A system analysis of a production system requires modeling tools that relate the various unit operations. Higher filling speeds for example impact downstream operations and the overall cost of the product. This project utilized an existing economic production model developed under a CRAMTD project. The model is based on an Excel spreadsheet that models the production system for the Polymeric Tray manufacturing and calculates the manufacturing cost per unit basis based on various production assumptions such as production schedule, rate and yield. It is a steady state model rather than a dynamic model which takes into account startup issues. At this particular phase, a steady state model is more appropriate as we are not trying to fine tune an existing operation, but rather trying to identify overall relationships between various unit operations and the effects on production cost.

## **Assumptions**

The results of any kind of modeling effort are greatly affected by the assumptions made regarding the production requirements, the production yields and efficiencies, and the methods used to calculate the cost. The results of the analysis are therefore more of a relative nature rather than of an absolute nature.

## **Production Scenario's**

Two basic scenarios were used for production requirements.

Scenario 1 is based on peace time requirements of 900,000 trays annually. The production is split between three producers with similar production capabilities. It is assumed that the producer will have an 8 hour production shift operation, five days per week and up to 48 weeks/year and that the production rate needs to take place within a 50% plant utilization rate. This means that the product can be produced within a 6 month time frame.

Scenario 2 is based on war time requirements of 8,800,000 trays to be produced in a 215 day period. The production is split between three producers with similar capabilities. It is assumed that the producer will have a three shift operation, six days a week.

## **Production Cost Calculations**

The production cost is a compilation of both fixed cost and variable cost. Fixed costs are items that are independent of the production rate such as equipment depreciation, maintenance and repair, taxes, insurance, etc. Variable costs are items that are directly related to the production rate, such as raw material cost, labor, utilities, etc. In calculating the impact of the fixed cost items on the production cost, assumptions need to be made if the production line is dedicated to only the polymeric tray ration product or if the production line is used during the "idle" time to produce other products. In the later case the fixed cost component will be shared between both products. In our calculations we looked at both cases. In Cost Case A (unlimited production), we assume that the producer has civilian products that make use of the line when ever it is not being used for military production and the fixed cost will be prorated based on time utilization

In Cost Case B (limited production), we assume hat the producer has a dedicated line for the polymeric tray production and that all fixed cost needs to be paid by the ration.

## **Product Yield and Process Efficiencies**

For each unit operation, assumptions need to be made regarding the efficiencies of process operations: eg what percent of the scheduled production time will equipment not be available for production.

For each step in the process, assumptions need to be made what the yield of the process is: eg how much product is lost during a process operation either due to defective product or due to material losses/shrinkage.

## **Material Cost**

Estimates were made for the product and package material cost associated with the production of Pork Sausage in Brine and Creamed Ground Beef. Vendors were requested to give us pricing information based on production type volumes. In cases where we were not able to obtain a quote, a best guess was made based on historical and comparable information. Somewhat lower pricing can probably be obtained via long term contract negotiations. It was assumed that both the precooked pork sausage and the precooked ground beef would be obtained from outside sources rather than manufacturing these ingredients in house.

## **Labor Cost**

Estimates were made for labor requirements to support the production of the polymeric half steam table tray product. Certain labor requirements are production rate sensitive, such as the inspection process of trays. The labor requirements for these operations were programmed as a function of the production rate and cycle time requirements. The cost of labor was estimated based on local wages. Wages in other parts of the country might differ.

## **Capital Equipment**

Estimates were made for the capital equipment that is needed for the production of a polymeric half steam table tray product. It was anticipated that the retort equipment would be the capacity limiting factor in this production line and was programmed into the model as a function of production rate and retort cycle time. It was assumed that all other capital equipment would be able to support high speed manufacturing. The purchase of capital equipment leads to other cost such as installation, instrumentation, infra structure, etc. Standard factors that can be found in engineering hand books were used to estimate the associated cost with

new capital equipment in order to estimate the total capital investment needs. Building cost or rent were not estimated in this model.

## Utility Cost

Utility cost was added to the model as a place holder at this time and no relationships were setup to make utility cost a function of production rate. A total utility cost of approximately \$69,000 per year was estimated at this time. Further refinements of the model in this area could consider to increase the functionality of the model.

## Manufacturing Cost

Manufacturing cost is the cost that can be associated to the production of the product. The manufacturing cost is built up from two components, the variable cost component and the fixed cost component. The variable cost component includes raw material and packaging material cost as well as labor cost and utility cost. The fixed cost component includes those cost that can be associated with the capital equipment such as depreciation, maintenance, operating supplies, taxes, insurance, financing cost, rent, etc. The percentage numbers used for these calculations are based on numbers used in engineering handbooks and practical experience in the food industry. A 7% overhead cost was added to the subtotal of the fixed and variable cost in order to calculate the total manufacturing cost.

The total manufacturing cost was used to calculate the manufacturing cost per product unit, in this case one tray. Two cost scenario's were used to make these calculation. **Unlimited Production** assumes the producer to produce this product year around at the same rate and be able to sell the excess product to commercial customers (Case A). **Limited Production** assumes that the producer has a dedicated facility in which he will only produce the ration and shut the line down when the contract requirements are met (Case B). In reality, the producer might be able to produce under a mixed case scenario in which certain parts of the process and capital equipment can be used for the production of alternate products.

## Base Case

Appendix A contains the cost calculations of a base case, scenario 1 (peace time) in which the production line speed is set at 10 trays a minute both for the pork sausage in brine and for the creamed ground beef. The production schedule is based on one shift per day, five days/week and the output requirements of 300,000 cans per producer. Retort cycle times were estimated for each product using Stock 1100 retorts in a static configuration (192 minutes for Creamed Ground Beef and 105 minutes for Sausage in Brine). The first cost number is based on the unlimited production assumption, the second cost number, higher cost number, is based on the limited production assumption

Manufacturing Cost of Creamed Ground Beef: \$14.065/21.975, using 12 retorts

Manufacturing Cost of Sausage in Brine: \$12.863/18.697, using 7 retorts

Appendix B contains the cost calculations of the base case, scenario 2 (war time) in which the production line speed is set at 15 trays/min and the same retort cycle times are used. The production schedule is now based on three shifts per day, six days/week and the output requirements have increased to 3,000,000 containers per producer which needs to be produced in over a 31 week time frame

Manufacturing Cost of Creamed Ground Beef: \$10.851/11.434, using 17 retorts

Manufacturing Cost of Sausage in Brine: \$10.452/10.867, using 10 retorts

## Cost Breakdown

The breakdown the manufacturing cost for the war time scenario, shows that 81-85% of the cost is determined by the "total direct production cost", or variable cost component (see fig 1 and 2). Figure 3 shows a further breakdown of this total direct production cost number and shows that about 37% of this variable cost number is attributed to container and cartoning cost. Figure 4 shows the breakdown of the fixed cost component. The majority of the fixed cost component is associated with the retort equipment.

**Manufacturing Cost Breakdown  
Limited Production  
War Time Scenario  
figure #2**

**Total Direct Production Cost Breakdown  
figure #3**

## Retort Equipment

Reducing the retort resource requirements has a significant impact on the manufacturing cost calculation. There are several common ways to lessen the retort resource requirement:

- rotate product during sterilization cycle to forced convective flows,
- use higher retort temperatures in conjunction with rotation,
- utilize starches or alternate product formula's that enhance (forced) convective flows within the tray
- use higher initial product temperatures
- allow higher residual gas levels in container to assist in forced convective flows during rotational retort cycle

It is anticipated that the retort cycle time can be reduced with as much as 30 to 50% in the majority of products, using the above techniques. This will reduce the required fixed cost component accordingly and regaining the retort capacity that currently can be obtained using the metal half steam table tray. The major concern is however the integrity of the tray and lid stock during these retort cycles. Special retort racks that clamp the tray within a pocket without allowing movement and causing abrasion defects is required. This requirement was considered during the design of the current used retort racks for polymeric trays. Also lid stock which can withstand higher retort temperatures to prevent delamination will be required. The quad laminate seems to be able to full fill this requirement

## Comparisons (What If Analysis)

The following tables demonstrate comparisons between production line speed, retort cycle time and post retort inspection yield, using economic model under the war time scenario.

Table #1 compares the number of retorts required as function of the retort cycle time and packaging line speed.

Table #1	Retort Cycle Time			
Packaging Line Speed	80 min	120 min	160 min	200 min
10 trays/minute	5	7	10	12
15 trays/minute	7	11	14	18
20 trays/minute	10	14	19	24
25 trays/minute	12	18	24	29
30 trays/minute	14	21	28	35

Table #2a compares the manufacturing cost of Creamed Ground Beef (limited production cost scenario) as function of the retort cycle time and packaging line speed:

Table #2a	Retort Cycle Time			
Packaging Line Speed	80 min	120 min	160 min	200 min
10 trays/minute	\$10.849	\$10.977	\$11.214	\$11.342
15 trays/minute	\$10.763	\$11.049	\$11.242	\$11.498
20 trays/minute	\$10.929	\$11.186	\$11.507	\$11.850
25 trays/minute	\$10.977	\$11.362	\$11.765	\$12.086
30 trays/minute	\$11.081	\$11.546	\$11.995	\$12.459

Table #2b compares the manufacturing cost of Creamed Ground Beef (unlimited production cost scenario) as function of the retort cycle time and packaging line speed:

Table #2b	Retort Cycle Time			
Packaging Line Speed	80 min	120 min	160 min	200 min
10 trays/minute	\$10.789	\$10.907	\$11.128	\$11.246
15 trays/minute	\$10.429	\$10.616	\$10.733	\$10.891
20 trays/minute	\$10.360	\$10.478	\$10.625	\$10.794
25 trays/minute	\$10.230	\$10.371	\$10.530	\$10.648
30 trays/minute	\$10.172	\$10.325	\$10.462	\$10.614

Table #3a compares the manufacturing cost of Creamed Ground Beef (limited production cost scenario) as function of the second inspection yield and the packaging line speed

Table #3a	Post Retort Inspection Yield			
Packaging Line Speed	94%	96%	98%	100%
10 trays/minute	\$11.705	\$11.520	\$11.342	\$11.172
15 trays/minute	\$11.787	\$11.607	\$11.434	\$11.268
20 trays/minute	\$12.137	\$11.958	\$11.786	\$11.621
25 trays/minute	\$12.370	\$12.192	\$12.022	\$11.859
30 trays/minute	\$12.742	\$12.565	\$12.395	\$12.232

Table #3b compares the manufacturing cost of Creamed Ground Beef (unlimited production cost scenario) as function of the second inspection yield and the packaging line speed

Table #3b	Post Retort Inspection Yield			
Packaging Line Speed	94%	96%	98%	100%
10 trays/minute	\$11.654	\$11.446	\$11.246	\$11.053
15 trays/minute	\$11.243	\$11.043	\$10.851	\$10.667
20 trays/minute	\$11.153	\$10.955	\$10.765	\$10.582
25 trays/minute	\$11.007	\$10.812	\$10.624	\$10.445
30 trays/minute	\$10.976	\$10.781	\$10.595	\$10.416

## Conclusion

The economic model and analysis clearly demonstrates that the retort operation is the most capital intensive part of the process and becomes the bottle neck of the process when number of retorts available is limited. More than likely the available retort capacity in a plant will dictate the packaging line speed. Therefore, the emphasis of this project needs to focus on increasing the capacity retort process. As a second objective we should ensure that line speeds of up to 20 trays per minute are achievable without affecting the process yield.

# **1 Introduction**

Since the inception of the Tray Pack Ration, the product has been packaged in a heavy metal tray shaped can with a double seamed metal lid and processed in non rotary, batch retort systems. Due to the declining supplier base for the metal tray can and lid and various problems with the interior coating of the cans, an alternative package was developed utilizing a polymeric tray body with a laminated foil and polymer lidstock. The change over to this particular container has a significant impact on the number of containers that can be processed in each retort batch. A larger foot print of the container flange and the requirement that the weight of each container needs to be supported by a racking mechanism rather than by stacking the containers on top of each other reduces the capacity approximately 33%.

The reduction in batch capacity can be offset, if the process cycle time can be reduced by the same percentage. This project investigates the impact of selected process and product parameters on the heat penetration rate of the product and the required process time to render the product commercial sterile.

## **2 Objective**

Conduct a process study to determine the impact of sauce viscosity on the required retort cycle time to yield commercial sterile product.

## **3 Product and Package Description**

Creamed Ground Beef, the product that was used in this study, complies with the Contract Technical Requirement dated January 11, 2000.

The precooked ground beef used for this study was manufactured by St James Gourmet, Farmingdale NY. The ground beef was partial precooked, frozen and packed in cryovac bags by the supplier for easier handling. The ground beef was re-blanching at the FMT facility to avoid excessive weight loss during the retort process and thinning of the sauce. Also, the precooking/blanching process removed excessive fat and juices, which otherwise might yield an unacceptable product.

Two different cream sauces were made according to the recommended formula in the product specification with the exception that the starch quantity was reduced from 6% to 5.5% (see table below). The two starches that were used for this experiment are: Purity W<sup>®</sup> and Thermtex<sup>®</sup>, both from National Starch, Bridgewater NJ. Two other main ingredients: "Dry Cream" and "Shortening" were manufactured by respectively Quality Ingredients, Burnsville MN (Quali-Cream 7211) and Kerry Inc, Beloit WI (NDX-112 V, Item No. I1529). Sauce formula II with Thermtex, had also Titanium dioxide (0.2%) to make the sauce less dark in a rotating retort process.

Ingredient	Sauce Formula I Code: P-W	Sauce Formula II Code: T-T
Water	83.10%	82.90%
Starch, Purity W	5.50%	0.00%
Starch, Thermtex	0.00%	5.50%
Shortening, powder	3.25%	3.25%
Onion Powder	1.50%	1.50%
Salt	1.50%	1.50%
Soup stock, dehydrated	0.75%	0.75%
Worcester sauce	0.25%	0.25%
Titanium dioxide	0.00%	0.20%
Pepper, White	0.15%	0.15%

Both Purity-W and Thermtex are modified food starches, the difference between the two starches is the temperature that is required to fully develop the starch structure. Purity-W develops its full viscosity at the batching temperature of 180 F, while Thermtex will partially develop its viscosity at batching temperatures and thus yielding a low initial viscosity sauce, allowing for fast heat penetration rates. Thermtex develops its full viscosity during the retort process, providing approximately the same high final viscosity after the retort process than Purity-W. This starch is therefore ideally suited for many canned food systems where optimum heat penetration and high final viscosity are required.

The trays used in this experiment were manufactured by Rexam Containers, Union MO and are identified as "Military Steam Table Tray, Type I". The tray weighs approximately 155 grams with a minimal wall thickness of 0.037".

The tray was sealed under vacuum conditions with a Quad laminate film. The film was manufactured by Smurfit Flexible packaging, Schaumburg, IL and is identified as " LC Flex 70466, Green".

## **4 Process Description:**

Both cream sauces were made in a jacketed kettle, equipped with high speed mixer and scrape surface agitator using the following procedure:

- 1) Mix required quantity of starch in small quantity of cold water and mix vigorously to form a thin slurry.
- 2) Add remaining quantity of cold water to kettle.
- 3) Add Dry Cream to kettle and mix vigorously (speed setting: 2) till all dissolved.
- 4) Add remaining ingredients (except starch slurry) to kettle and mix while heating kettle till product reaches 180 F to 190 F. Use high heat setting
- 5) Add starch slurry and the final mixture should be heated to 180 F to 190 F and held at this temperature for 5 minutes. (Use low heat setting once 180 F is reached)
- 6) If product needs to be refrigerated, cool product to 90 F and pump into buckets. Label buckets with material ID and Lot Number. Place product in refrigerator.

The precooked ground beef was blanched at out facility to remove excessive fat and juices from the ground beef. The ground beef was then drained and mixed with the refrigerated cream sauce at a ration of 32 oz of ground beef to 60 oz of cream sauce.

The trays were filled to a net weight of 92 oz. The trays intended for heat penetration studies were equipped with a thermocouple that was placed in the middle of the tray and held in place by a 1.5" diameter spacer disk which was placed near the end of the thermocouple. The thermocouples used for the heat penetration study were manufactured by Ecklund-Harrison technology, Ft. Myers FL. and are identified as "Needle Type Thermocouple", (4-3/4" long), type CNL.

The filled trays were placed in the sealing carriers of the Raque Heat Sealer and sealed at a speed of approximately 8 trays/min. while seal conditions were maintained at 412 F for 6.5 seconds. The vacuum condition was a variable in this study, and was controlled by a vacuum timer that opened a vacuum valve for a preset duration. A vacuum time of 1.0 seconds resulted in an approximate vacuum of 20" Hg in the sealing chamber, yielding trays that had a pre-retort residual gas level of less than 175 cc. A vacuum time of 0.17 seconds resulted in an approximate vacuum of 10" Hg in the sealing chamber, yielding trays that had a pre-retort residual gas level of approximately 350 cc.

The sealed trays with thermocouples were loaded "face up" in the front cage of a Stock 1100, four cage Rotomat, using polymeric tray racks specifically designed for this tray. The trays were placed in layers 4 through 9 (two cans per layer). Additional trays without thermocouples were also placed within these layers and retorted to yield samples for post process product evaluation. All remaining rack pockets were filled with ballast trays (trays filled with water). The other three cages of the retort were filled with ballast boxes. The polymeric tray racks used in this study were manufactured by Stock America, Grafton, WI and are identified as "7333A". The design features of this rack allowed the trays to be loaded either "face up" or "face down", and the tray are locked into the pocket so that they can be rotated during the retort process without creating abrasion defects.

Two retort programs were developed and used in this study. One program was designed for a static process. Program #20 processed the tray "up-side-down". The other program was designed for a rotational process. Program #23 rotated the trays at a speed of 15 rpm. Both retort programs used the same temperature and pressure profile. The temperature of the retort was set at 254 F during the Come Up Phase (S2) and at 252 F during the Hold Phase (S3). Copies of the retort programs can be found in the Appendix I.

The heat penetration data was collected during the process via a system supplied by Ellab Inc, Copenhagen DN. The main components of the system were a 16 channel slip ring assembly, an Analog/Digital converter (CMC) and Ellab CMC software, which had the ability to calculate the  $F_0$  values on-line. The data was analyzed using Ellab's "Eval Basic" software, version 1.20.

The heating phase of the retort process was terminated after all thermocouples had reached an  $F_0$  value of greater or equal to 6.0 min. The cooling phase was terminated after all thermocouples indicated a temperature lower or equal to 120 F.

## 5 Full Factorial Experimental Design:

A full factorial design was adopted to investigate the effect of vacuum applied during sealing and retort rotation speed. Post Retort Residual Gas, Post Retort Product Consistency and the required Cooking Time (CT) of the product were measured/calculated as response variables.

### Static Mode:

Parameters	Levels		Response
Product Formulation	Regular Starch (P-W)	High Temperature Starch (T-T)	Residual Gas, Product Consistency & CT (Cook Time)
Vacuum applied	20" (targeting 150 cc residual gas)	10" (targeting 350 cc residual gas)	

### Rotational Mode:

Parameters	Levels		Response
Product Formulation	Regular Starch (P-W)	High Temperature Starch (T-T)	Residual Gas, Product Consistency & CT (Cook Time)
Vacuum applied	20" (targeting 150 cc residual gas)	10" (targeting 350 cc residual gas)	

The total number of experiments required to determine the main effects and interactions for the above two factors was 4 ( $=2^2$ ) for each mode. Each experiment would contain 10 to 12 trays with thermocouples and at least one additional tray without thermocouple. Each experiment would be repeated at least once.

## 6 Data Analysis

Using Ball's heat penetration assumptions, each thermocouple lead data was analyzed for the typical heating factors<sup>1</sup> such as  $jh$ ,  $fh$ ,  $xbh$ ,  $f2$ . These heating factors were then used to calculate the required Cook Time to reach a Lethality of  $F_0 = 6.0$  min, using a Retort Temperature of 250 F and an Initial Product Temperature of 80 F. The Cook Time variable was then used for statistical analysis.

Each tray with a thermocouples was also analyzed for post-retort residual gas level. This measurement was performed by opening the tray below water and capturing the "free air" in an inverted graduate cylinder. This post-retort residual gas data was the used for statistical analysis.

One of the trays without thermocouple was analyzed for product consistency. This measurement was done by heating the product, draining the sauce from the ground beef in a #7 sieve and measuring the consistency in a Bostwick Consistometer. Due to the limited data, data is reported "as is" and no statistical analysis could be performed.

All statistical analysis was based on the outputs from SAS software<sup>4</sup>, SAS Institute Inc and StatGraphics version 5.0<sup>5</sup>. The statistical procedures used in the analysis were General Linear Model (GLM), Multifactor ANOVA, and the Univariate procedures.

### 6.1 Refinement of Data

The analysis procedure started by refining the raw data by removing the outliers through two-stage refinement process. The first stage removed the outliers based on residual gas model. Observations with absolute standardized residual values (based on Residual Gas model) greater than 2 were removed from the data file.

**Note:** Outliers due to residual gas might have been caused by variation during the sealing process, either due to a sticking valve or a leaking seal chamber. It was

deemed prudent to remove these outliers in order to minimize the impact of excessive variation in residual gas on subsequent analysis.

During the second stage, removing outliers based on the Cook Time model further refined the output from the first stage. The same criteria was used to discard observation with absolute standardized residual values (based on the Cook Time model) greater than 2.

**Note:** The exact location of the thermocouple within container can have a significant effect on the heat penetration rate. Outliers in the Cook Time model might have been caused by shifting of spacer disk during packaging and retort loading, causing an improperly located thermocouple. It was deemed prudent to remove these outliers in order to minimize the impact of incorrect located thermocouples.

The refined data was then used for subsequent analysis of variance and is reported in the following section.

**Note:** It should be noted that none of the conclusions reached in the analysis would have been reversed if the outliers would not have been removed.

## 6.2 Results

### 6.2.1 Static Mode

#### 6.2.1.1 Residual Gas Analysis:

The data was first analyzed for post retort Residual Gas level by using a multifactor ANOVA analysis. Summary data, obtained from the SAS output can be found in Appendix-II. Based on this data we can conclude that:

- The overall F-test was significant at 99% confidence level, indicating that the model as a whole accounts for a significant portion of variability in the response variable (Residual Gas).
- The F-test for Starch and Vacuum was also significant at 99% confidence level, indicating the means for the different starch types and vacuums are not equal.
- The interaction between Starch Types and Vacuum was significant at 99% confidence level.

Multiple comparison test (Tukey Test) was used to compare between the two starch types and the two levels of vacuum. The test indicated, that the vacuum applied during sealing had a significant impact on the residual gas level inside the tray after retorting. However, the test also indicated (at 0.05 significance level) that the post retort Residual Gas value was significantly affected by the starch type. The residual gas level was significantly higher when using starch T-T. Because the trays were filled and sealed with a different product formulation, it can not be assumed that there would have been no significant difference between pre-retort residual gas levels inside the tray under the same vacuum conditions. Product formulation might have affected the headspace in the container and thus the pre retort residual gas level..

Tukey Grouping	Mean	N	Starch
A	268.6	30	T-T
B	199.3	42	P-W

\*Means with the same letter are not significantly different.

Tukey Grouping	Mean	N	Vacuum
A	334.7	32	10"
B	142.9	40	20"

\*Means with the same letter are not significantly different.

Means Analysis per Treatment:

Starch Type	Level of Vacuum	N	Residual Gas			
			R-Square CV	Mean	SD	CV
P-W	10"	18	0.967	316.9	23.6	0.07
P-W	20"	24	0.083	111	14	0.13
T-T	10"	14		357.5	17.9	0.05
T-T	20"	16		190.8	20.6	0.11

#### 6.2.1.2 Cook Time Analysis

The refined data was then analyzed for Cook Time using a multifactor ANOVA analysis.

Summary data, obtained from the SAS output can be found in Appendix-II. Based on this data we can conclude that:

- The overall F-test was significant at 99% confidence level, indicating that the model as a whole accounts for a significant portion of variability in the response variable (Cooking Time).
- The F-test Starch Type was significant at 99% confidence level, indicating the means at the different Starch Types (P-W and T-T ) are not equal.
- The F-test for Vacuum was significant at 99% confidence level, indicating the means at the different Vacuum Levels are not equal.
- The interaction between Starch Type and Vacuum was significant at 99% confidence level.

Multiple comparison test (Tukey Test) was used to compare between the different levels of vacuum. The output from the test (at 0.05 significance level) indicated that we have a lower CT value (faster heating) when the tray was processed sealed under a 20" vacuum (~150 cc) and when using Starch P-W.

Tukey Grouping	Mean	N	Starch
A	85.8	30	T-T
B	80.4	42	P-W

Tukey Grouping	Mean	N	Vacuum
A	89.8	32	10"
B	78.0	40	20"

\*Means with the same letter are not significantly different.

The data was then analyzed for the mean value per treatment (combination of Starch Type and Vacuum). As one can see from the table below and from the accompanying graph that Starch T-T with a low vacuum level (10") results in the longest Cook Time while Starch P-W with a high vacuum level (20") results in the shortest Cook Time.

6.2.1.2.1 Means Analysis per Treatment:

Starch Type	Level of Vacuum	N	CT			
			R-Square CV	Mean	SD	CV
P-W	10"	18	0.905 0.028	86.6	2.8	0.03
P-W	20"	24		75.8	1.9	0.02
T-T	10"	14		93.8	2.1	0.02
T-T	20"	16		78.7	2.4	0.03

Interaction Plot

#### 6.2.1.3 Model Assessment:

The R-Square value=0.90 in the ANOVA Table is evidence of a good fit is provided by the model. This value indicates that 90% of the variability in CT can be explained when Starch Type and Vacuum level are used as independent variables.

#### Assessing Normality:

The value of 0.89 for Shapiro-Wilk test and Normal Probability Plot below support the assumption of normality.

#### Accessing of Equality of Variance:

The Plot of Studentized Residual \* Predicted CT shows a plot of residuals vs. predicted values of CT . Based on this plot, there is no strong evidence for unequal variances and for outliers. This means that our methodology for refining the data was successful.

## 6.2.2 Dynamic Mode:

### 6.2.2.1 Residual Gas Analysis:

The data was first analyzed for post retort Residual Gas level by using a multifactor ANOVA analysis. Summary data, obtained from the SAS output can be found in Appendix-II. Based on this data we can conclude that:

- The overall F-test was significant at 99% confidence level, indicating that the model as a whole accounts for a significant portion of variability in the response variable (Residual Gas).
- The F-test for Starch Type and Vacuum was also significant at 99% confidence level, indicating the means for the different starch types and vacuums are not equal.
- The interaction between Starch Type and Vacuum was not significant at 95% confidence level.

Multiple comparison test (Tukey Test) was used to compare between the two starch types and the two levels of vacuum. The test indicated, that the vacuum applied during sealing had a significant impact on the residual gas level inside the tray after retorting. However, the test also indicated (at 0.05 significance level) that the post retort Residual Gas value was significantly affected by the starch type. The residual gas level was significantly higher when using starch T-T. Because the trays were filled and sealed with a different product formulation, it can not be assumed that there would have been no significant difference between pre-retort residual gas levels inside the tray under the same vacuum conditions. Product formulation might have affected the headspace in the container and thus the pre retort residual gas level..

Tukey Grouping	Mean	N	Starch
A	236.2	37	T-T
B	176.1	55	P-W

\*Means with the same letter are not significantly different.

Tukey Grouping	Mean	N	Vacuum
A	290.1	44	10"
B	117.8	48	20"

\*Means with the same letter are not significantly different.

### **Means Analysis per Treatment:**

Starch Type	Level of Vacuum	N	Residual Gas			
			R-Square CV	Mean	SD	CV
P-W	10"	24	0.963	271.4	18.7	0.07
P-W	20"	31	0.088	102.2	14.0	0.14
T-T	10"	20		312.5	21.7	0.07
T-T	20"	17		146.3	16.7	0.11

### **Interaction Plot**

#### **6.2.2.2 Cook Time Analysis**

The refined data was then analyzed for Cook Time using a multifactor ANOVA analysis.

Summary data, obtained from the SAS output can be found in Appendix-III. Based on this data we can conclude that:

- The overall F-test was significant at 99% confidence level, indicating that the model as a whole accounts for a significant portion of variability in the response variable (Cooking Time).
- The F-test Starch Type was significant at 99% confidence level, indicating the means at the different Starch Types (P-W and T-T ) are not equal.
- The F-test for Vacuum was significant at 99% confidence level, indicating the means at the different vacuum levels are not equal.
- The interaction between Starch Type and Vacuum was not significant at 95% confidence level.

Multiple comparison test (Tukey Test) was used to compare between the different levels of vacuum. The output from the test (at 0.05 significance level) indicated that we have a lower CT value (faster heating) when the tray was processed sealed under a 10" vacuum (~350 cc) and when using Starch T-T.

Tukey Grouping	Mean	N	Starch
A	34.6	37	T-T
B	49.3	55	P-W

Tukey Grouping	Mean	N	Vacuum
A	38.1	44	10"
B	48.2	48	20"

\*Means with the same letter are not significantly different.

The data was then analyzed for the mean value per treatment (combination of Starch Type and Vacuum). As one can see from the table below and from the accompanying graph that Starch T-T with a low vacuum level (10") results in the shortest Cook Time while Starch P-W with a high vacuum level (20") results in the longest Cook Time.

#### 6.2.2.2.1 Means Analysis per Treatment:

Starch Type	Level of Vacuum	N	CT			
			R-Square CV	Mean	SD	CV
P-W	10"	24	0.917 0.059	44.1	2.8	0.06
P-W	20"	31		53.3	2.6	0.05
T-T	10"	20		30.9	1.4	0.04
T-T	20"	17		38.9	3.2	0.08

Interaction Plot

Interaction Plot

#### 6.2.2.3 Model Assessment:

The R-Square value=0.92 in the ANOVA Table is evidence of a good fit is provided by the model. This value indicates that 92% of the variability in CT can be explained when Starch Type and Vacuum level are used as independent variables.

#### Assessing Normality:

The large value of 0.92 for Shapiro-Wilk test and Normal Probability Plot below support the assumption of normality.

#### Assessing of Equality of Variance:

The Plot of Studentized Residual \* Predicted CT shows a plot of residuals vs. predicted values of CT. Based on this plot, there is no strong evidence for unequal variances and for outliers. This means that our methodology for refining the data was successful.

### 6.2.3 Comparisons of Static and Dynamic Retort Processing

#### 6.2.3.1 Residual Gas

It was observed that there was a significant reduction in post retort residual gas level when one switches from static (program 20) to dynamic (program 23) retort processing. It is hypothesized that more air is "consumed" by, or more air incorporated into the product during a rotational retort process when more product is exposed to the "headspace" inside the can.

Program	Vacuum [inches Hg]	Post Process Residual Gas [cc]	
		P-W	T-T
Static	10	317	358
	20	111	191
Dynamic	10	271	313
	20	102	146

#### 6.2.3.2 Product Color

The sauce color darkened significantly during rotational retort processing. However, samples submitted to The US Army Natick Soldier Center, Group Ration Team at Natick of Sauce Formula I were still rated as "acceptable". The darkening of the sauce color can be compensated by using "titanium dioxide" in the sauce formulation which was used in Sauce Formula II. Samples of this product still have to be evaluated by The US Army Natick Soldier Center, Group Ration Team.

#### 6.2.3.3 Product Consistency

Rotational retort processing had a significant impact on the consistency of the product after retorting as can be seen in the table below. Consistency is measured by the distance the sauce travels during a 10 second time frame. Therefore rotational retort process leads to a thinner sauce. Samples submitted to The US Army Natick Soldier Center, Group Ration Team at Natick were rated as "acceptable"

Program	Vacuum [inches Hg]	Brookfield Viscosity Sauce before retorting [cP] <sup>1</sup>	Consistency [cm/10 sec]
20, Sauce Formula I	10	21,400	4.3
	20	21,400	4.4
20, Sauce Formula II	10	7,200	5.0
	20	7,200	5.0
23, Sauce Formula I	10	21,400	6.4
	20	21,400	7.1
23, Sauce Formula II	10	7,200	4.8
	20	7,200	4.7

<sup>1)</sup> Brookfield Digital Viscometer, model RVTDV-I, spindle #5, 10 rpm

## 7 Conclusions

The statistical analysis indicate that:

- Post retort residual gas is affected by the formulation used and by the retort process applied
- The calculated cook time based on heating factors is significantly impacted by the vacuum condition/residual gas inside the tray, by the retort rotation, and by the type starch used in the sauce formulation
- The slowest formulation, packaging and retort condition is a high temperature starch packed in a low vacuum condition and processed in a static mode
- The fastest formulation, packaging and retort condition is a high temperature starch packed in a low vacuum condition and processed in a rotational mode.
- Use of a high temperature starch, eg a starch that builds it's viscosity during the retort cook cycle, is most desirable when a rotational retort process is being considered.
- Relaxation of the product specification has economic benefits when a rotational retort process is being considered as long as it can be established that the quality of the product is not negatively affected.

# 1 Introduction

Since the inception of the Tray Pack Ration, the product has been packaged in a heavy metal tray shaped can with a double seamed metal lid and processed in non rotary, batch retort systems. Due to the declining supplier base for the metal tray can and lid and various problems with the interior coating of the cans, an alternative package was developed utilizing a polymeric tray body with a laminated foil and polymer lid stock. The change over to this particular container has a significant impact on the Manufacturability of the product. Double rolled seams are replaced by fusion seals and contamination of seal area is more likely to result in seal defects. On the other hand, it is expected that the over all through put rate of a heat sealer can exceed that of a can seamer for the half steam table tray.

The sensitivity of seal contamination to seal defects, requires a thorough understanding of the interactions of process, product and packaging variables. This study documents these interactions and gives guidance to the producers in selecting process, product and packaging parameters that optimize the yield of the process and therefore minimize the cost of the product. This study also highlights the interactions the specification limits that might affect the manufacturability of the product.

## 2 Objective

Investigate the effect of selected product, process and packaging parameters in a filling and sealing process on the quality of the seal using "Pork Sausage Links in Brine".

### **3 Product and Package Description:**

Pork Sausage Links in Brine used in this study complied with the Contract Technical Requirement dated January 11, 2000 with the exception that the water was used instead of brine.

The sausage links were manufactured by ASE Deli/Foodservice Company, St. Charles, IL. and are the same as used by current producers of "Pork Sausage Links in Brine" for Combat Feed Program. The sausage links were precooked by the supplier in order to avoid excessive weight loss during the retort process and each weighs approximately 20 grams before retorting. The sausage dimensions are approximately 3 " long and 1/2 to 3/4" in diameter. Each tray was filled with 72 Sausage Links which were placed in two layers, each layer containing three rows of 12 sausages.

The trays used in these experiments were manufactured by Rexam Containers, Union MO and are identified as "Military Steam Table Tray, Type I". The tray weighs approximately 155 grams with a minimal wall thickness of 0.037".

The tray was sealed under vacuum conditions with a Quad laminate film. The film was manufactured by Smurfit Flexible packaging, Shaumburg, IL and is identified as " LC Flex 70466, Green".

### **4 Process Description**

The trays were manual filled with sausage links, three rows/layer of approximately 12 sausages/row, two layers. The trays were then weight and its net weight adjusted to 1440 - 1460 gram by adding or subtracting a sausage link. The trays were then placed on the filling conveyor of the Raque Heat Seal line. The seals were wiped with alcohol to remove any "grease" stains in the seal area that might have occurred during the filling and handling process. The tray was conveyed to the Raque heat sealer and automatically loaded in the carriers of the sealer. Once in the carrier, water was added to the tray, by the Oden liquid filling system, to ensure that the net

weight target was met (90 oz or 96 oz). The Oden system used two pumps and two nozzles to deliver the required volume of water. Speed of the Oden system was adjusted to match the Tray line speed. The seals were then wiped by a single person with a paper towel. The tray was conveyed at a speed of 8 or 15 trays/min. while seal conditions were maintained at 412 F for 2.5 or 3.5 seconds. The vacuum condition was controlled by a vacuum timer that opened a vacuum valve for a preset duration. A vacuum time of 1.0 seconds resulted in an approximate vacuum of 20" Hg in the sealing chamber. A vacuum time of 0.2 seconds resulted in an approximate vacuum of 10" Hg in the sealing chamber.

Table #1 displays the four setups of various timer settings that were used during the experiments to control the Raque Heat Seal operation.. There are three operations occurring in the sealer: "Evacuation", "Sealing" and "Vacuum Release". Each operation has two timers, a delay timer and a process timer. The delay timer of each operation starts at the same time, eg at closing of the seal chamber. After the delay timer is timed out, the process timer starts. After the process timer for the sealing operation has timed out, the chamber opens. This means that all operations, including the Vacuum release needs to be completed by the end of the sealing operation. The operation of the Raque heat sealer requires that the vacuum is released during the sealing cycle and therefore does not allow the seal to "set" before the vacuum can be released. This will of course increase the capacity of the sealer but might also cause seal wrinkles due to tension in the lid material. It means that the equipment relies on a mechanical seal between the internal and exterior of the container during the sealing process to maintain the residual gas level. While the seal chamber is brought back to atmospheric pressure, the internal container must remain under the "vacuum condition" in order to control the residual gas level inside the container.

The table also estimates the maximum line speed that could be achieved in any of the timer setups. Using setup #3 with the longest vacuum and seal time reduced the maximum line speed to 15 trays/min which was the highest line speed used in these experiments

	Setup #1	Setup #2	Setup #3	Setup #4
Vacuum Delay [sec]	0.1	0.1	0.1	0.1
Vacuum Process [sec]	1.0	0.2	1.0	0.2
Sealing Delay [sec]	1.3	0.5	1.3	0.5
Sealing Process [sec]	2.5	2.5	3.5	3.5
Vent Delay [sec]	1.5	0.7	1.5	0.7
Vent Process [sec]	2.3	2.3	3.3	3.3
Max Cap [Trays/Min]	19	24	15	21

After the sealing process, the trays were inspected for seal defects as identified in MIL-PRF-32004A, (Dated 5-MAR-01). A limited number of trays were evaluated for residual gas content. The data was then analyzed for the response variables residual gas and defective tray. The response variable "defective tray", could either be caused by a critical, major or minor defect, such as open seal (critical) or minor anomaly (minor).

To increase the efficiency of the experiment and cut down on the cost of the raw materials, the sausages were several times reused by draining them from their water and placing them in new trays for the following experiment. Small absorption of water by the sausage was compensated by reducing the water added during the liquid fill operation.

## 5 Fractional Factorial Experimental Design:

The objective of the experiments was to investigate the effect of the factors on the responses by using two levels (low and high) for every factor. Analysis of the results would reveal the most important factors that can then be investigated in a Phase II experimental study to determine in more detail the interactions between those variables and the optimal values for these factors.

Initially the following variable were selected for this experimental design:

- ☐ Product Fill Weight
- ☐ Product Temperature
- ☐ Line Speed
- ☐ Vacuum Time
- ☐ Seal Time

After initial test in December 2000, it was determined that the high temperature product samples caused moisture condensation in the seal area which then led to a high percentage of seal anomalies, even though the seals were clean and dry before entering into the sealing section of the Raque Heat Sealer. It was decided to eliminate this variable from the experimental design and concentrate the efforts on the remaining variables.

Factors	Pork Sausage		Response
	Levels		
Product fill weight, oz	90	98	R1: Number of defective trays R2: Residual gas
Line speed, trays / min	8	15	
Vacuum Time, sec.	0.2	1.0	
Sealing Time, sec.	2.5	3.5	

The total number of experiments for a full factorial designed study to determine the main effects and interactions for the Pork Sausage would require 16 experiments ( $2^4 = 16$ ). It was decided to utilize a fractional factorial of  $1/2$  to reduce the number of experiments to 8 experiments to be more efficient with the resources.

The experimental plan and the results of the runs can be found in Appendix I.

## 6 Data Analysis

### 6.1 Residual Gas Data

From each experiment, six trays were selected for residual gas evaluation. The set of six consisted of four consecutive trays, one of each sealing head, and two random selected trays. The Average and Standard Deviation of residual gas for each experiment is reported in the table below

Note: The standard deviation in residual gas was higher than expected and observed in previous experiments. It is expected that the seal chambers leak rate had increased and that a review of the chamber tightness is required.

#### Means Analysis per Treatment:

RUN	FILL WEIGHT	SPEED	VAC TIME	SEAL TIME	Res Gas Avg	Res Gas Std
PSA	90	8	1	3.5	202.00	16.15
PSB	90	8	0.2	2.5	358.33	40.82
PSC	90	15	1	2.5	193.00	32.64
PSD	90	15	0.2	3.5	334.17	33.23
PSI	98	8	1	2.5	136.00	44.47
PSJ	98	8	0.2	3.5	201.00	36.63
PSK	98	15	1	3.5	147.67	45.56
PSL	98	15	0.2	2.5	209.17	26.72

### 6.1.1 Residual Gas Data Analysis

#### 6.1.1.1 Summary

The data was first analyzed for pre-retort Residual Gas level by using a multifactor ANOVA analysis. Summary data, obtained from the StatGraphics output can be found in Appendix-II.

Based on this data we can conclude that:

- The overall F-test was significant at 99% confidence level, indicating that the model as a whole accounts for a significant portion of variability in the response variable (Residual Gas).
- The F-test for Fill Weight, and Vacuum Time were all significant at 99% confidence level. Indicating the means for the different Fill Weight, and Vacuum Time were not equal.
- The F-test for Seal Time and Line Speed were not significant at 90% confidence level. Indicating that the means for the different Seal Time and Line Speed were equal.

#### 6.1.1.2 Product Fill Weight

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Fill Weight. The test indicated, as expected, that the Fill Weight had a significant impact on the Residual Gas level. Higher fill weight, and consequently less headspace, resulted in a lower Residual Gas level. Fill weight variation will therefore result in a significant variation of residual gas level.

Also, higher fill weights will require less vacuum in order to meet the specified maximum residual gas level.

LSD Grouping	Mean	N	Fill Weight, oz
A	173.5	24	98
B	271.8	24	90

\*Means with the same letter are not significantly different.

### Means and 95.0 Percent LSD Intervals

#### 6.1.1.3 Vacuum Time

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Vacuum. The test indicated, as expected, that the residual gas is significantly effected by the vacuum. Stronger Vacuum, and consequently less gas in the headspace, resulted in lower Residual gas level.

As a result, the vacuum timer should be used as the primary control variable to adjust the residual gas level and to compensate for differences in fill weight and product temperature.

LSD Grouping	Mean	N	Vacuum Time, sec.
A	169.6	24	1.0
B	275.6	24	0.2

\*Means with the same letter are not significantly different.

### Means and 95.0 Percent LSD Intervals

#### 6.1.1.4 Line Speed

Multiple comparison test (LSD Test) at 90% confidence level was used to compare between the two levels of Line Speed. The test indicated, as expected, that the residual gas is not significantly effected by the Line Speed.

#### 6.1.1.5 Seal Time

Multiple comparison test (LSD Test) at 90% confidence level was used to compare between the two levels of Seal Time. The test indicated, as expected, that the residual gas is not significantly effected by the Seal Dwell Time.

#### 6.1.1.6 Product Temperature

This variable was omitted form the experimental design due to known moisture condensation problems in the seal area. It is unlikely that this product will be filled at elevated temperatures as the pork sausage is refrigerated and the brine most likely is made from "tap" water.

#### 6.1.1.7 Second Order Interactions

Next, an Anova Analysis was done using the three most important factors: Fill Weight, Vacuum and Speed, to estimate the second order interactions between these factors and the response variable "residual gas". The data of this analysis can also be found in Appendix II. The only

second order interaction that was significant was the interaction between Fill Weight and Vacuum Time on Residual Gas. Second Order Interactions between the other factors on Residual Gas were not statistical significant. The second order interaction indicates that the effect of fil weight is greater when the vacuum timer was set to 0.2 seconds

### Residual Gas Interaction

FILL WEIGHT [oz]	VAC TIME [sec]	Res Gas Avg [cc]	Res Gas Std [cc]
98	1.0	142	43
98	0.2	205	31
90	1.0	198	25
90	0.2	346	38

## 6.2 Seal Defects Data:

All the sealed trays were inspected for various defects in the seal area. One or more defects in the seal, either critical, major or minor resulted in a defective tray. The most severe defect was used to log as the reason for the defective tray. The percent defective trays per treatment is reported in the table below

RUN	FILL WEIGHT	SPEED	VAC TIME	SEAL TIME	Total No. of Defect Trays	Total No. of Trays	% Defective
PSA	90	8	1	3.5	3	48	0.06
PSB	90	8	0.2	2.5	11	48	0.23
PSC	90	15	1	2.5	25	48	0.52
PSD	90	15	0.2	3.5	12	48	0.25
PSI	98	8	1	2.5	16	48	0.33
PSJ	98	8	0.2	3.5	3	48	0.06
PSK	98	15	1	3.5	10	48	0.21
PSL	98	15	0.2	2.5	20	48	0.40

### 6.2.1 Defective Tray Analysis

#### 6.2.1.1 Summary

The data was analyzed by using a multifactor ANOVA analysis. Summary data, obtained from the StatGraphics output can be found in Appendix-III. Based on this data we can conclude that:

- The F-test for the parameters: Line Speed and Seal Time were significant at 99% confidence level, indicating the means at the different factor levels were not equal.
- The F-test for Fill Weight, and Vacuum Time were not significant at 90% confidence level, indicating the means at the different Fill Weight, and Vacuum Time were not different.

#### 6.2.1.2 Line Speed

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between two different Line Speeds. The output from the test indicated that a lower defect rate can be achieved at the lower Line Speed of 8 trays/min. There are two reasons identified for this behavior. The first reason for this is that the seal area is "contaminated" during the brine fill. A higher line speed requires faster fluid flow, more splashing and thus more contamination. The second reason is attributed to the wiping of the seal area before it enters the sealing chamber. The faster line runs, the less time the wiper has to clean/dry these flanges. High speed manufacturability needs to focus on a liquid delivery system that minimizes the splashing on the seals.

LSD Grouping	Mean	N	Line Speed, trays/min
A	0.34	192	15
B	0.17	192	8

\*Means with the same letter are not significantly different.

### Means and 95.0 Percent LSD Intervals

#### 6.2.1.3 Seal Time

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Seal Time.. The output from the test indicated a lower defect rate when the tray was sealed with a 3.5 second dwell time. The longer seal dwell times tend to push out the top layer of molten poly propylene, and in case where there is moisture entrapment, it also tends to push out this moisture. The moisture is burned off and what ever moisture remains tend to form small anomalies that are located in a ridge on the inside of the seal. Anomalies on the inside of the seal were not scored as we do not consider this to be part of the first 1/16" of the seal.

LSD Grouping	Mean	N	Seal Time, sec.
A	0.14	192	3.5
B	0.36	192	2.5

\*Means with the same letter are not significantly different.

Means and 95.0 Percent LSD Intervals

#### 6.2.1.4 Vacuum Time

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Vacuum Time.. The output from the test indicated that the defect rate was not significantly effected by the vacuum time

#### 6.2.1.5 Product Fill Weight

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Fill Weight.. The output from the test indicated that the defect rate was not significantly effected by the fill weight.

#### 6.2.1.6 Product Temperature

This variable was omitted from the study

#### 6.2.1.7 Second Order Interactions

Next, an Anova Analysis was performed on the data using three factors, line speed, seal time, and vacuum. The only significant second order interaction that was established is the interaction between seal time, vacuum time and defective trays. At shorter seal times (2.5 seconds) the effect of vacuum is much greater than when seal times of 3.5 seconds are used. It is clear that longer seal times are recommended to make the process less sensitive to the vacuum

Vacuum Time	Seal Time	Percent Defective
0.2	3.5	15.6
1.0	3.5	13.5
0.2	2.5	31.3
1.0	2.5	42.7

## 7 Conclusions:

- Pre retort residual gas is affected by the fill weight and the vacuum applied. It should be noted that the fill temperature would also have had a significant effect. However this variable was omitted from the study due to it's severe negative effect on seal quality
- Seal defects were mainly affected by the line speed and by the seal time. Increased line speed increased the seal defects. This is caused by the higher liquid fill speed and thus more splashing into the seal area, and the in-ability of a seal wiper to keep up with wiping the tray

seal lid dry. Increased seal time did reduce the problems of moisture entrapment of the seal. The moisture is pushed to the outside edges of the seal. In case of the 3.5 sec seal time, most seal defects were minor anomalies located at the inner edge of the seal. Followed by a nice, clean wide seal.

- Of lesser or no effect were fill weight, and vacuum time. It was expected that a higher vacuum and lower fill weight could cause "vacuum wrinkles in the seal area. Some evidence was found to this extend but it could not be proven to be statistical significant. There is however a possibility that these effects are hidden due to the much larger effect of line speed and seal time.
- Even though Product Temperature was omitted from this study, it was concluded in preliminary experiments that the best product temperature is ambient temperature. If the product is too warm, it will create a high humidity headspace that condenses in the seal area. If the product is too cold, the tray might cool down to the point that the ambient air condenses on the seal. In either case, moisture is incorporated in the seal area and anomalies are created.
- The recommended condition for filling and sealing is:
  - Line Speed: 8 trays/min
  - Fill Weight: 90-98 oz, no significant effect
  - Vacuum Time: 0.2 - 1.0 sec, no significant effect
  - Seal Time: 3.5 seconds
  - Product Temperature: ambient temperature. Too hot or too cold will cause condensation problems

## **Appendix I**

### **Experimental Plan and Results for Pork Sausage in Brine**

## **Production**

### **Sausage Links in Brine**

Prior to the production day 500 lbs of sausages will be defrosted. At the day of production 100 trays will be filled with sausages (72 links per tray). On a need basis these trays will be placed on the conveyor belt and fed into the Raque Sealer. Each tray will be filled with the required quantity of brine, evacuated and sealed at the required production speed. Random samples will be taken from the experiment for QC testing (residual gas and net weight). The lid of the remaining containers will be removed by cutting the lid on the inside of the seal area. The sausages will be drained from the brine, removed from the tray and placed into a new tray. A test will be made to establish if and how much the net weight has increased of these already used sausages and an adjustment will be made in the brine filling system in order to target the same net weight. Above process can be repeated till four runs have been made. Product will be discarded at end of the day. If new sausages need to be used to compensate for losses during the previous experiment, the tray will be filled with a small amount of water equivalent to the water that was absorbed (if any) by the already used sausages. The produced containers will be cleaned and inspected for seal defects at a later date.

## Subset Analysis

### Analysis Summary

Data variable: RESIDGAS  
Code variable: RUN

Number of observations: 48  
Number of levels: 8

### The StatAdvisor

-----  
This procedure calculates summary statistics for the values of RESIDGAS corresponding to each of the 8 levels of RUN. It also creates a variety of plots and allows you to save the calculated statistics. Further analyses can be performed on the data using the Oneway Analysis of Variance procedure under Compare on the main menu.

### Summary Statistics

# Multiple Regression Analysis

Dependent variable: RESIDGAS

Parameter	Estimate	Standard Error	T Statistic	P-Value
CONSTANT	1472.79	148.265	9.93352	0.0000
FILL WEIGHT	-12.3021	1.51033	-8.14528	0.0000
SPEED	-0.47619	1.72609	-0.275877	0.7840
VAC TIME	-132.5	15.1033	-8.7729	0.0000
SEAL TIME	-2.91667	12.0827	-0.241393	0.8104

## Analysis of Variance

Source	Sum of Squares	Df	Mean Square	F-Ratio	P-Value
Model	251298.0	4	62824.4	35.86	0.0000
Residual	75331.2	43	1751.89		
Total (Corr.)	326629.0	47			

R-squared = 76.9368 percent

R-squared (adjusted for d.f.) = 74.7913 percent

Standard Error of Est. = 41.8556

Mean absolute error = 30.1389

Durbin-Watson statistic = 2.14131 (P=0.1470)

Lag 1 residual autocorrelation = -0.0719767

## The StatAdvisor

The output shows the results of fitting a multiple linear regression model to describe the relationship between RESIDGAS and 4 independent variables. The equation of the fitted model is

$$\text{RESIDGAS} = 1472.79 - 12.3021 \cdot \text{FILL WEIGHT} - 0.47619 \cdot \text{SPEED} - 132.5 \cdot \text{VAC TIME} - 2.91667 \cdot \text{SEAL TIME}$$

Since the P-value in the ANOVA table is less than 0.01, there is a statistically significant relationship between the variables at the 99% confidence level.

The R-Squared statistic indicates that the model as fitted explains 76.9368% of the variability in RESIDGAS. The adjusted R-squared statistic, which is more suitable for comparing models with different numbers of independent variables, is 74.7913%. The standard error of the estimate shows the standard deviation of the residuals to be 41.8556. This value can be used to construct prediction limits for new observations by selecting the Reports option from the text menu. The mean absolute error (MAE) of 30.1389 is the average value of the residuals. The Durbin-Watson (DW) statistic tests the residuals to determine if there is any significant correlation based on the order in which they occur in your data file. Since the P-value is greater than 0.05, there is no indication of serial autocorrelation in the residuals.

In determining whether the model can be simplified, notice that the highest P-value on the independent variables is 0.8104, belonging to SEAL TIME. Since the P-value is greater or equal to 0.10, that term is not statistically significant at the 90% or higher confidence level. Consequently, you should consider removing SEAL TIME from the model.

# Multifactor ANOVA - RESIDGAS

## Analysis Summary

Dependent variable: RESIDGAS

Factors:

FILL WEIGHT  
SEAL TIME  
SPEED  
VAC TIME

Number of complete cases: 48

## The StatAdvisor

-----  
This procedure performs a multifactor analysis of variance for RESIDGAS. It constructs various tests and graphs to determine which factors have a statistically significant effect on RESIDGAS. It also tests for significant interactions amongst the factors, given sufficient data. The F-tests in the ANOVA table will allow you to identify the significant factors. For each significant factor, the Multiple Range Tests will tell you which means are significantly different from which others. The Means Plot and Interaction Plot will help you interpret the significant effects. The Residual Plots will help you judge whether the assumptions underlying the analysis of variance are violated by the data.

## Analysis of Variance for RESIDGAS - Type III Sums of Squares

Source	Sum of Squares	Df	Mean Square	F-Ratio	P-Value
-----					
MAIN EFFECTS					
A:FILL WEIGHT	116230.0	1	116230.0	66.35	0.0000
B:SEAL TIME	102.083	1	102.083	0.06	0.8104
C:SPEED	133.333	1	133.333	0.08	0.7840
D:VAC TIME	134832.0	1	134832.0	76.96	0.0000
RESIDUAL	75331.2	43	1751.89		
-----					
TOTAL (CORRECTED)	326629.0	47			
-----					

All F-ratios are based on the residual mean square error.

## The StatAdvisor

-----  
The ANOVA table decomposes the variability of RESIDGAS into contributions due to various factors. Since Type III sums of squares (the default) have been chosen, the contribution of each factor is measured having removed the effects of all other factors. The P-values test the statistical significance of each of the factors. Since 2 P-values are less than 0.05, these factors have a statistically significant effect on RESIDGAS at the 95.0% confidence level.

Table of Least Squares Means for RESIDGAS  
with 95.0 Percent Confidence Intervals

#### The StatAdvisor

-----  
This table shows the mean RESIDGAS for each level of the factors. It also shows the standard error of each mean, which is a measure of its sampling variability. The rightmost two columns show 95.0% confidence intervals for each of the means. You can display these means and intervals by selecting Means Plot from the list of Graphical Options.

#### Multiple Range Tests for RESIDGAS by FILL WEIGHT

Method: 95.0 percent LSD				
FILL WEIGHT	Count	LS Mean	LS Sigma	Homogeneous Groups
98	24	173.458	8.54373	X
90	24	271.875	8.54373	X
-----				
Contrast			Difference	+/- Limits
90 - 98			*98.4167	24.3671

\* denotes a statistically significant difference.

#### The StatAdvisor

-----  
This table applies a multiple comparison procedure to determine which means are significantly different from which others. The bottom half of the output shows the estimated difference between each pair of means. An asterisk has been placed next to 1 pair, indicating that this pair shows a statistically significant difference at the 95.0% confidence level. At the top of the page, 2 homogenous groups are identified using columns of X's. Within each column, the levels containing X's form a group of means within which there are no statistically significant differences. The method currently being used to discriminate among the means is Fisher's least significant difference (LSD) procedure. With this method, there is a 5.0% risk of calling each pair of means significantly different when the actual difference equals 0.

Dependent variable: RESIDGAS

Factors:

SPEED  
FILL WEIGHT  
VAC TIME

Number of complete cases: 48

## The StatAdvisor

This procedure performs a multifactor analysis of variance for RESIDGAS. It constructs various tests and graphs to determine which factors have a statistically significant effect on RESIDGAS. It also tests for significant interactions amongst the factors, given sufficient data. The F-tests in the ANOVA table will allow you to identify the significant factors. For each significant factor, the Multiple Range Tests will tell you which means are significantly different from which others. The Means Plot and Interaction Plot will help you interpret the significant effects. The Residual Plots will help you judge whether the assumptions underlying the analysis of variance are violated by the data.

## Analysis of Variance for RESIDGAS - Type III Sums of Squares

Source	Sum of Squares	Df	Mean Square	F-Ratio	P-Value
MAIN EFFECTS					
A:SPEED	133.333	1	133.333	0.11	0.7454
B:FILL WEIGHT	116230.0	1	116230.0	93.19	0.0000
C:VAC TIME	134832.0	1	134832.0	108.11	0.0000
INTERACTIONS					
AB	2106.75	1	2106.75	1.69	0.2010
AC	261.333	1	261.333	0.21	0.6495
BC	21930.7	1	21930.7	17.58	0.0001
RESIDUAL	51134.4	41	1247.18		
TOTAL (CORRECTED)	326629.0	47			

All F-ratios are based on the residual mean square error.

## The StatAdvisor

The ANOVA table decomposes the variability of RESIDGAS into contributions due to various factors. Since Type III sums of squares (the default) have been chosen, the contribution of each factor is measured having removed the effects of all other factors. The P-values test the statistical significance of each of the factors. Since 3 P-values are less than 0.05, these factors have a statistically significant effect on RESIDGAS at the 95.0% confidence level.

## Table of Least Squares Means for RESIDGAS with 95.0 Percent Confidence Intervals

	Std.	Lower	Upper

98 0.2	12	205.083	10.1947	184.495	225.672
98 1	12	141.833	10.1947	121.245	162.422

#### The StatAdvisor

This table shows the mean RESIDGAS for each level of the factors. It also shows the standard error of each mean, which is a measure of its sampling variability. The rightmost two columns show 95.0% confidence intervals for each of the means. You can display these means and intervals by selecting Means Plot from the list of Graphical Options.

#### Multiple Range Tests for RESIDGAS by SPEED

Method: 95.0 percent LSD				
SPEED	Count	LS Mean	LS Sigma	Homogeneous Groups
15	24	221.0	7.20874	X
8	24	224.333	7.20874	X
Contrast				
		Difference		+/- Limits
8 - 15		3.33333		20.5886

\* denotes a statistically significant difference.

#### The StatAdvisor

This table applies a multiple comparison procedure to determine which means are significantly different from which others. The bottom half of the output shows the estimated difference between each pair of means. There are no statistically significant differences between any pair of means at the 95.0% confidence level. At the top of the page, one homogenous group is identified by a column of X's. Within each column, the levels containing X's form a group of means within which there are no statistically significant differences. The method currently being used to discriminate among the means is Fisher's least

significant difference (LSD) procedure. With this method, there is a 5.0% risk of calling each pair of means significantly different when the actual difference equals 0.

## **1. Introduction**

Since the inception of the Tray Pack Ration, the product has been packaged in a heavy metal tray shaped can with a double seamed metal lid and processed in non rotary, batch retort systems. Due to the declining supplier base for the metal tray can and lid and various problems with the interior coating of the cans, an alternative package was developed utilizing a polymeric tray body with a laminated foil and polymer lidstock. The change over to this particular container has a significant impact on the Manufacturability of the product. Double rolled seams are replaced by fusion seals and contamination of seal area are more likely to result in seal defects. On the other hand, it is expected that the over all through put rate of a heat sealer can exceed that of a can seamer for the half steam table tray.

The sensitivity of seal contamination to seal defects, requires a thorough understanding of the interactions of process, product and packaging variables. This study documents these interactions and gives guidance to the producers in selecting process, product and packaging parameters that optimize the yield of the process and therefore minimize the cost of the product. This study attempts to also high light via the same interactions the specification limits that might affect the manufacturability of the product.

## **2. Objective:**

Investigate the effect of selected product, process and packaging parameters in a filling and sealing process on the quality of the seal using "Creamed Ground Beef".

### **3. Product and Package Description:**

Creamed Ground Beef used in this study, complies with the Contract Technical Requirement dated January 11, 2000.

The precooked ground beef used for this study was manufactured by St James Gourmet, Farmingdale NY. The ground beef was partial precooked, frozen and packed in bags by the supplier for easier handling. The ground beef was re-blanching at the FMT facility to avoid excessive weight loss during the retort process and thinning of the sauce. Also, the precooking/blanching process removed excessive fat and blood, which otherwise might yield an unacceptable dark product. The cream sauce was made according to the recommended formula in the product specification with the exception that the starch quantity was reduced from 6% to 5.5%. The three main ingredients: "Starch", "Dry Cream" and "Shortening" were manufactured by respectively National Starch, Bridgewater NJ (Purity W or ThermTex), Quality Ingredients, Burnsville MN (Quali-Cream 7211) and Kerry Inc, Beloit WI (NDX-112 V, Item No. I1529).

The trays used in these experiments were manufactured by Rexam Containers, Union MO and are identified as "Military Steam Table Tray, Type I". The tray weighs approximately 155 grams with a minimal wall thickness of 0.037".

The tray was sealed under vacuum conditions with a Quad laminate film. The film was manufactured by Smurfit Flexible packaging, Schaumburg, IL and is identified as " LC Flex 70466, Green".

### **4. Process Description:**

The cream sauce was made in a jacketed Groen Kettle, equipped with high speed mixer and scrape surface agitator using the following procedure (batch size 400 lbs):

- 1) Mix required quantity of starch in small quantity of cold water and mix vigorously to form a thin slurry.

- 2) Add remaining quantity of cold water to kettle.
- 3) Add Dry Cream to kettle and mix vigorously (speed setting: 2) till all dissolved.
- 4) Add remaining ingredients (except starch slurry) to kettle and mix while heating kettle till product reaches 180 F to 190 F. Use high heat setting
- 5) Add starch slurry and the final mixture should be heated to 180 F to 190 F and held at this temperature for 5 minutes. (Use low heat setting once 180 F is reached)

The Creamed Ground Beef was made in the Groen Kettle by adding the beef to the already made sauce (~180 F).

- 6) Add refrigerated precooked ground beef to the sauce and mix with scrape surface agitator till uniformly blended (215 lbs)
- 7) Heat/Cool blend as required to obtain product temperature required for the experiment
- 8) Pump blend to the Raque single piston filler hopper.

The trays were placed on the filling conveyor of the Raque Heat Seal Line. The Raque Single Piston Filler filled the tray to either a net weight of 92 or 100 oz. The trays were then conveyed to the Raque Heat Sealer and automatically loaded in the carriers of the sealer. Once in the carrier, the seals were inspected and when necessary wiped. The tray was conveyed at a speed of 8 or 15 trays/min. while seal conditions were maintained at 412 F for either 2.5 or 3.5 seconds. The vacuum condition was controlled by a vacuum timer that opened a vacuum valve for a preset duration. A vacuum time of 1.0 seconds resulted in an approximate vacuum of 20" Hg in the sealing chamber. A vacuum of 0.2 seconds time resulted in an approximate vacuum of 10" Hg in the sealing chamber.

Table #1 displays the various timer settings used for the Raque Heat Sealer. There are three operations occurring in the sealer: "Evacuation", "Sealing" and "Vent". Each operation has two timers, a delay timer and a process timer. The delay timer of each operation starts at the same time, eg at closing of the seal chamber. After the delay timer is timed out, the process timer starts. After the process timer for the sealing operation has timed out, the chamber opens. This means that all operations, including the Vent needs to be completed by the end of the sealing operation. The operation of the Raque heat sealer requires that the vacuum is released during the sealing cycle and therefore does not allow the seal to "set" before the vacuum can be released. This will of course increase the capacity of the sealer but might also cause seal wrinkles due to tension in the lid material. It also means that the equipment relies on a mechanical seal between the internal and exterior of the container during the sealing

process. The seal chamber is brought back to atmospheric pressure while the internal container must remain under the "vacuum condition" in order to control the residual gas level inside the container.

The table also estimates the maximum line speed that could be achieved in any of the timer setups. Using setup #3 with the longest vacuum and seal time reduced the maximum line speed to 15 trays/min which was the highest line speed used in these experiments.

	Setup #1	Setup #2	Setup #3	Setup #4
Vacuum Delay [sec]	0.1	0.1	0.1	0.1
Vacuum Process [sec]	1.0	0.2	1.0	0.2
Sealing Delay [sec]	1.3	0.5	1.3	0.5
Sealing Process [sec]	2.5	2.5	3.5	3.5
Vent Delay [sec]	1.5	0.7	1.5	0.7
Vent Process [sec]	2.3	2.3	3.3	3.3
Max Capacity [Trays/Min]	19	24	15	21

After the sealing process, the trays were inspected for seal defects as identified in MIL-PRF-32004A, (Dated 5-MAR-01). A limited number of trays were evaluated for residual gas content. The data was then analyzed for the response variables residual gas and defective tray. The response variable "defective tray", could either be caused by a critical, major or minor defect, such as open seal (critical) or minor anomaly (minor).

To increase the efficiency of the experiment and cut down on the cost of the raw materials, the Creamed Ground Beef was several times reused by removing the product from the tray and adding it back to the blend kettle.

## 5. Fractional Factorial Experimental Design:

The objective of the experiments was to investigate the main effect of the factors on the response variables by using two levels (low and high) for every factor. Analysis of the results would reveal the most important factors that influence the response variables. These factors can then be further investigated in a Phase II experimental study to determine in more details the interactions between those variables and the optimal values for each of these factors.

The following variables were selected for this experiment design:

- ☐ Product Fill Weight
- ☐ Product Viscosity
- ☐ Product Temperature
- ☐ Line Speed
- ☐ Vacuum Time
- ☐ Seal Time

Factors	Creamed Ground Beef		Response
	Levels		
Product fill weight, oz	92	100	R1: Number of defective trays
Starch Type	Purity W	Therm Tex	
Product temperature, F	80	140	R2: Residual gas
Line speed, trays / min	8	15	
Vacuum Time, sec.	0.2	1	
Sealing Time, sec.	2.5	3.5	

The total number of experiments for a full factorial designed study to determine the main effects and interactions for Creamed Ground Beef is would require 64 ( $2^6 = 64$ ) experimental production runs. The time and expense of such would be such that it was decided to utilize a fractional factorial of 1/4 and reduce the number of experiments to 16 experiments to be more efficient with the resources.

The experimental plan and the results of these runs can be found in Appendix I

## 6. Data Analysis

### 6.1. Residual Gas Data

From each experimental run, six trays were selected for residual gas evaluation. The set of six consisted of four consecutive trays, one of each sealing head, and two random selected trays. The Average and Standard Deviation of the residual gas for each experiment is reported in the table below.

**Residual Gas Data per Treatment:**

RUN	FILL WEIGHT	Temp. F	SPEED	VAC TIME	SEAL TIME	Starch*	RG Mean	RG STDEV
CBA	92	80	8	1.0	3.5	1	143	13

### 6.1.1. Residual Gas Data Analysis

#### 6.1.1.1. Summary

The data was further analyzed for by using a multifactor ANOVA analysis. Summary data, obtained from the StatGraphics output can be found in Appendix-II. Based on this data we conclude that:

- The overall F-test was significant at 99% confidence level, indicating that the model as a whole accounts for a significant portion of variability in the response variable (Residual Gas).
- The F-test for Fill Weight, Product Temperature and Vacuum Time were all significant at 99% confidence level. Indicating the means for the different Fill Weight, Temperature and Vacuum Time are statistically not equal.
- The F-test for Speed was significant at 90% confidence level.
- The F-test for Seal Time and Starch Type were not significant at 90% confidence level. Indicating that the means for the different Seal Time and Starch Type are statistically equal.

#### 6.1.1.2. Fill Weight

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Fill Weight. The test indicates, as expected, that the residual gas level is significantly effected by the fill weight. Higher fill weight, and consequently less headspace,

resulted in a lower Residual Gas level. As a consequence, fill weight variation will result in a significant variation of residual gas.

As a result, higher fill weight will require less vacuum to meet the specified maximum residual gas level.

LSD Grouping	Mean	N	Fill Weight, oz
A	123.3	48	100
B	214.5	48	92

\*Means with the same letter are not significantly different.

#### 6.1.1.3. Product Temperature

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Product Temperature. The test indicates, as expected, that the residual gas level is significantly effected by the product temperature. Higher product temperature resulted in a lower Residual Gas level. There are two causes for this. First, the gas in the headspace is at approximately the same temperature as the product temperature, but the gas will "shrink" when it is measured at 70 F. Second, at the higher temperature, the vapor pressure of water increases and the gases in the headspace contain therefore more vapor which condenses out at lower temperature, thus reducing the residual gas level.

As result of high temperature filling, less vacuum will be required to meet the maximum head space requirements

LSD Grouping	Mean	N	Product Temperature, F
A	160.6	48	140
B	177.1	48	80

\*Means with the same letter are not significantly different.

#### 6.1.1.4. Vacuum

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Vacuum. As can be seen, the residual gas level is significantly effected by the Vacuum. Longer Vacuum Time and thus Stronger Vacuum, and consequently less gas in the headspace, resulted in a lower Residual Gas level.

As a result, the vacuum timer should be used as the primary control variable to adjust the residual gas level and to compensate for differences in fill weight and product temperature

LSD Grouping	Mean	N	Vacuum Time, sec.
A	92.2	48	1.0
B	245.5	48	0.2

\*Means with the same letter are not significantly different.

#### **6.1.1.5. Line Speed**

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Line Speed. The analysis indicated that, the residual gas level is not significantly effected by the Line Speed. When the confidence interval was dropped to 90%, the analysis did indicate a significant difference. This conclusion was unexpected but could be explained, at least partially, by a small deviation in the average fill weight for the two groups of experiments. The experiments with higher line speed had a slightly higher actual fill weight: (average fill weight: 2705 gram (8 trays/min) and 2715 gram (15 trays/min). This would contributed to at about half of the difference in residual gas level. Other factors might also have contributed, such as better alignment of between the seal heads and carriers at certain speeds and therefore less leakage.

#### **6.1.1.6. Product Viscosity**

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Product Viscosity. The analysis indicated that, the residual gas level is not significantly effected by the Product Viscosity. This result was as expected.

#### 6.1.1.7. Seal Time

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Seal Time. The analysis indicated that, the residual gas level is not significantly effected by the Seal Time. This result was as expected.

#### 6.1.1.8. Second Order Interactions

Next, an Anova Analysis was just done using the three most important factors to estimate the second order interactions between these factors and the response variable "residual gas". The data of this analysis can be found in Appendix II. The interaction between Fill Weight and Vacuum Time on Residual Gas are most significant, followed by interaction between Product Temperature and Vacuum Time on Residual Gas. The interaction between Fill Weight and Product Temperature on Residual Gas was not statistical significant. The tables and figures below show the average residual gas as function of the selected variables

Product Temp [F]	Vacuum Time [sec]	Avg Residual Gas [cc]
80	0.2	258
140	0.2	233
80	1.0	97
140	1.0	88

Fill Weight [oz]	Vacuum Time [sec]	Avg Residual Gas [cc]
92	0.2	286
100	0.2	205
92	1.0	143
100	1.0	41

Product Temp [F]	Fill Weight [oz]	Avg Residual Gas [cc]
80	92	220
140	92	209
80	100	134
140	100	112

## 6.2. Seal Defect Data

All the sealed trays were inspected for various defects in the seal area. A seal with one or more defects was considered to be a defective tray and would be removed from the line to be reworked. The most severe defect was used to log the reason for the defective tray. The percent defective tray for each experiment is reported in the table below.

### Defective Trays Analysis per Treatment:

RUN	FILL WEIGHT	Temp. F	SPEED	VAC. TIME	SEAL TIME	Starch*	No. of Defect. Trays	Total No. of Trays	% Defective
CBA	92	80	8	1	3.5	1	0	48	0.00
CBB	92	80	15	1	2.5	1	8	48	0.17
CBC	100	80	8	0.2	3.5	1	4	52	0.08

CBO	100	140	8	0.2	3.5	2	3	49	0.06
CBP	100	140	15	0.2	2.5	2	27	48	0.56

\*Starch Type: #1 : Purity W Starch  
#2 : ThermTex Starch

### 6.2.1. Defective Tray Data Analysis

#### 6.2.1.1. Summary

The data was analyzed on the number of defective trays in each experiment by using a multifactor ANOVA analysis. Summary data, obtained from the StatGraphics output can be found in Appendix-III. Based on this data we can conclude that:

- The F-test for the parameters: Fill Weight, Product Temp. and Seal Time were significant at 99% confidence level, indicating the means at the different factor levels are not equal.
- The F-test for Line Speed, Vacuum Time and Starch Type were not significant at 90% confidence level, indicating the means at the different Line Speed, Vacuum Time and Starch Type are not different.

#### 6.2.1.2. Fill Weight

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Fill Weight. The output from the test indicated a lower defect rate when the tray was sealed with 100 oz Fill Weight.. The reason for this is that the film is less stretched when the vacuum is released and can rest on the product.

LSD Grouping	Mean	N	Fill Weight, oz
A	0.227	375	100
B	0.313	403	92

\*Means with the same letter are not significantly different.

#### 6.2.1.3. Product Temperature

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Product Temperature.. The output from the test indicated a lower defect rate when the tray was sealed with product that had a temperature of 80 F. The reason for this is that higher product temperature caused moisture condensation in the seal area. This condensed moisture is then incorporated in the seal melt and when the seal pressure is released. At that time the incorporated moisture forms tiny steam bubbles, separating the film from the tray to form the so called anomalies

LSD Grouping	Mean	N	Product Temperature, F
A	0.46	399	140
B	0.076	379	80

\*Means with the same letter are not significantly different.

#### 6.2.1.4. Seal Time

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Seal Time.. The output from the test indicated a lower defect rate when the tray was sealed with a 3.5 second dwell time. The longer seal dwell times tend to push out the top layer of molten poly propylene, and in case where there is moisture entrapment, it

also tends to push out this moisture. The moisture is burned off and what ever moisture remains tend to form small anomalies that are located in a ridge on the inside of the seal. We did not score these as defects, as they were not part of the first 1/16" of the seal.

LSD Grouping	Mean	N	Seal Time, sec.
A	0.128	404	3.5
B	0.413	374	2.5

\*Means with the same letter are not significantly different.

#### **6.2.1.5. Vacuum**

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Vacuum. The analysis indicated that, the rate of defective trays is not significantly effected by the level of Vacuum.

#### **6.2.1.6. Line Speed**

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Line Speed. The analysis indicated that, the rate of defective trays is not significantly effected by the Line Speed.

#### 6.2.1.7. Product Viscosity

Multiple comparison test (LSD Test) at 95% confidence level was used to compare between the two levels of Product Viscosity. The analysis indicated that, the rate of defective trays is not significantly effected by the Product Viscosity.

#### 6.2.1.8. Second Order Interactions

Next, an Anova Analysis was just done using the three most important factors to determine the second order interactions between these factors and the response variable "Defective Tray". The data of this analysis can be found in Appendix III. The analysis shows that the interaction between Fill Weight and Product Temperature as well as Product Temperature and Seal Time on the rate of Defective Trays are significant (99% confidence interval), followed by interaction between Fill Weight and Seal Time on rate of Defective Trays (95% confidence interval).

## 7. Conclusions

- The pre-retort residual gas in the tray is primarily determined by the Vacuum, Fill Weight and Product Temperature
- The defective trays due to seal defects were primarily determined by Seal Time, Fill Weight and Product Temperature.
- Increased product temperature caused condensation in the seal is which lead to anomalies in the seal area.
- Increased seal time did reduce the problems of moisture entrapment of the seal. It appears that the moisture is pushed to the outside edges of the seal. In case of the 3.5 sec seal time, most seal defects were minor anomalies located at the inner edge of the seal, followed by a nice, wide seal.
- Higher Fill Weight tended to reduce the rate of defective trays. It is hypothesized that the film is less stretched, reducing the chance for delaminations and wrinkles
- Vacuum was not identified as the primary cause for defective trays. Good seals can be made under high vacuum as long as the fill weight is adequate to support the film after the vacuum is released.

## Filling Experiments

### Creamed Ground Beef

At the day of experiments, one batch of sauce for Creamed Ground Beef will be manufactured (400 lb). A sample of the sauce will be taken for viscosity measurement. Steam will be turned off and pre cooked ground beef will be added (215 lb). After the batch is uniformly mixed, the product temperature will be measured. The required temperature range will be 70-90 F for the 80 F product temperature condition and 130-150 F for the 140 F condition. The product will then be transferred via pump to the Raque filler as needed. Forty-eight trays will be filled and sealed for each experiment. Random samples will be taken from the experiment for QC testing (residual gas, net-weight). The lid of the remaining containers will be removed by cutting the lid on the inside of the seal area. The product will be removed from the container and dumped back into the final mixing kettle. The product is reheated to the required experimental temperature and the second run is made. Repeat above process till four runs have been made. Discard product at end of the day. The produced containers will be cleaned and inspected for seal defects at a later date.

# Multifactor ANOVA - RESIDGAS

## Analysis Summary

Dependent variable: RESIDGAS

Factors:

FILL WEIGHT  
SEAL TIME  
SPEED  
Starch  
Temp  
VAC TIME

Number of complete cases: 96

## The StatAdvisor

-----  
This procedure performs a multifactor analysis of variance for RESIDGAS. It constructs various tests and graphs to determine which factors have a statistically significant effect on RESIDGAS. It also tests for significant interactions amongst the factors, given sufficient data. The F-tests in the ANOVA table will allow you to identify the significant factors. For each significant factor, the Multiple Range Tests will tell you which means are significantly different from which others. The Means Plot and Interaction Plot will help you interpret the significant effects. The Residual Plots will help you judge whether the assumptions underlying the analysis of variance are violated by the data.

All F-ratios are based on the residual mean square error.

The StatAdvisor  
-----

The ANOVA table decomposes the variability of RESIDGAS into contributions due to various factors. Since Type III sums of squares (the default) have been chosen, the contribution of each factor is measured having removed the effects of all other factors. The P-values test the statistical significance of each of the factors. Since 4 P-values are less than 0.05, these factors have a statistically significant effect on RESIDGAS at the 95.0% confidence level.

#### The StatAdvisor

This table applies a multiple comparison procedure to determine which means are significantly different from which others. The bottom half of the output shows the estimated difference between each pair of means. There are no statistically significant differences between any pair of means at the 95.0% confidence level. At the top of the page, one homogenous group is identified by a column of X's. Within each column, the levels containing X's form a group of means within which there are no statistically significant differences. The method currently being used to discriminate among the means is Fisher's least significant difference (LSD) procedure. With this method, there is a 5.0% risk of calling each pair of means significantly different when the actual difference equals 0.

 The ANOVA table decomposes the variability of Combined into contributions due to various factors. Since Type III sums of squares (the default) have been chosen, the contribution of each factor is measured having removed the effects of all other factors. The P-values test the statistical significance of each of the factors. Since 6 P-values are less than 0.05, these factors have a statistically significant effect on Combined at the 95.0% confidence level.

## The StatAdvisor

-----  
 This table shows the mean Combined for each level of the factors. It also shows the standard error of each mean, which is a measure of its sampling variability. The rightmost two columns show 95.0% confidence intervals for each of the means. You can display these means and intervals by selecting Means Plot from the list of Graphical Options.

# **Production Report**

## **STP#1022**

### **1. CORANET Demo Site Process and Packaging Equipment**

#### **1.1. The Coranet Demonstration Site**

The CORANET Demonstration site is located at the Rutgers University Food Manufacturing Technology Facility at 120 New England Avenue in Piscataway, New Jersey. The facility is equipped with commercial packaging lines (Tiromat Horizontal Form Fill Seal equipment for MRE's and a Raque Heat Sealer for polymeric trays) along with product preparation and filling equipment as well as retort equipment. This equipment is able to demonstrate full scale production of Combat Rations. The CORANET Demonstration Site was used to produce two different Polymeric Tray products (Pork Sausage in Brine and Creamed Ground Beef) under different residual gas levels and retort conditions. After completion of the production run, products were sent to the US Army Natick Soldier Center for package integrity and organoleptic analysis.

#### **1.2. Oden Filler**

The Oden filler, model: 6-Head Pro/Fill 3000, is a six head pump filler with electronic controls for fill speed, fill volume and nozzle cut off adjustment. The filler can either be gravity fed from a hopper (used for Brine's, Gravy's and low viscosity Sauces) or for the more viscous products via a pressurized manifold system (used for Stew type products). The pressurized manifold system is part of the re-circulation system of the final blend kettle.

#### **1.3. Raque Single Piston Filler**

The Raque, model PF2.5-1 is a single piston filler with a hopper (non jacketed, no agitation) and is designed to fill highly viscous sauces and products with particulates. This filler covers a wide range of fill volumes (100 cc to 3400 cc) and has different pistons and nozzles to support this wide range in fill volumes and variety in products.

#### **1.4. Raque Heat Sealer**

The Raque Heat Sealer, serial number 93-285-C, is used to evacuate and seal the polymeric tray. The sealer is a continuous motion sealer with four moving seal chambers with a designed maximum capacity of 30 trays/min. Actual maximum capacity might however be limited by vacuum and seal time parameters. The continuous motion, rather than an indexing motion, allows the filling and sealing of the tray with very thin liquids, such as pork sausage links in brine without sloshing of the brine into the seal area. Each sealing head uses a 5" bore, 3 stage air cylinder, which creates (@ 80 psig air pressure) a seal plate force of 3950 lbf (2" rod inside cylinder).

The operation of the Raque Heat Sealer is controlled by various timers. There are three operations occurring in the sealer: "Evacuation", "Sealing" and "Vent". Each operation has two timers, a delay timer and a process timer. The delay timer of each operation starts at the same time, eg at closing of the seal chamber. After the delay timer is timed out, the process timer starts. After the process timer for the sealing operation has timed out, the chamber opens. This means that all operations, including the Vent needs to be completed by the end of the sealing operation. The operation of the Raque heat sealer requires that the vacuum is released during the sealing cycle and therefore does not allow the seal to "set" before the vacuum

is released. This increases the capacity of the sealer but might also cause seal wrinkles due to tension in the lid material when the vacuum is released.

The table below displays the actual maximum throughput capacity (trays/min) of the Raque Heat Sealer as function of seal time and vacuum time.

Vacuum Time Seal Time	0.2 sec	1.0 sec	1.5 sec
2.5 sec	24	19	17
3.0 sec	21	17	15
3.5 sec	18	15	13
4.0 sec	16	13	12
4.5 sec	14	12	11

### **1.5. Stock Retort**

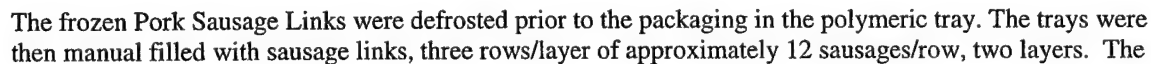

The retort equipment used for this production contract was a Stock model 1100 four cage retort with an Icon-2000 version 2 control system. The retort is a full water immersion cooker with over pressure capability and rotation during all process phases. This retort can process up to 192 polymeric trays per load, using a specially designed rack that supports the tray during rotation. Cycle times are a function of the retort conditions and the product and were determined by a process authority for both a static and a rotational process prior to the production runs.

### 2.1. Product Description

The sausage links were manufactured by ASE Deli/Foodservice Company, St. Charles, IL. and are the same as used by current producers of "Pork Sausage Links in Brine" for Combat Feed Program. The sausage links were precooked by the supplier in order to avoid excessive weight loss during the retort process and each weighs approximately 20 grams before retorting. The sausage dimensions are approximately 3 " long and 1/2 to 3/4" in diameter.

The tray was sealed under vacuum conditions with a Quad laminate film. The film was manufactured by Smurfit Flexible packaging, Shaumburg, IL and is identified as " LC Flex 70466, Green".

## Process Flow Sheet Sausage Links

trays were weighed and its net weight adjusted to 1440 - 1460 gram by adding or subtracting a sausage link. This method yielded trays with either 72 or 73 links. The trays were then placed on the filling conveyor of the Raque Heat Seal line. The seals were wiped with alcohol to remove any "grease" stains in the seal area that might have occurred during the filling and handling process. Instead of using brine, approximately 25-27 grams of salt was added separately to each tray. The trays were then conveyed to the Raque heat sealer and automatically loaded in the carriers of the sealer. Once in the carrier, water was added to the tray, by the Oden liquid filling system, to ensure that the net weight target was met (90 oz). The Oden system used two pumps and two nozzles to deliver the required volume of water in two stages. The fill speed of the Oden system was adjusted to match the Tray line speed. After the liquid fill, the tray flange area was wiped with a paper towel to remove water spatters that were created by the liquid filling system. The tray was conveyed at a speed of 4 trays/min. while seal conditions were maintained at 412 F for 3.5 seconds. The residual gas inside the tray is determined by vacuum condition at seal time and was controlled by a vacuum timer that opened a vacuum valve for a preset duration.

The Pork Sausage Links were packaged on Raque Heat Seal packaging line under various vacuum conditions. The objective of the production run was to seal product samples a three different residual gas levels:

- 150 cc headspace
- 250 cc headspace
- 350 cc headspace

After the product was sealed in the containers, it was sterilized in either a still full water immersion retort process, or a rotational full water immersion retort process according to a process determined by a process authority.

Each container was visually inspected after the retort process, inserted into a carton sleeve and packed in a lined shipping case.

## 2.3. Production Data

This product was packaged and sterilized on 8/16/01 and 8/22/01

### 2.3.1. Packaging Data

- Lot Code: 1228A, 1.0 sec vacuum, 150 cc target, still retort
- Lot Code: 1228B, 0.4 sec vacuum, 250 cc target, still retort
- Lot Code: 1234A, 0.17 sec vacuum, 350 cc target, still retort
- Lot Code: 1234B, 0.17 sec vacuum, 350 cc target, rotational retort
- Lot Code: 1234C, 0.4 sec vacuum, 250 cc target, rotational retort
- Lot Code: 1234D, 1.0 sec vacuum, 150 cc target, rotational retort

### **3. Creamed Ground Beef**

#### **3.1. Product Description**

Creamed Ground Beef used in this study, complies with the Contract Technical Requirement dated January 11, 2000.

The precooked ground beef used for this study was manufactured by St James Gourmet, Farmingdale NY. The ground beef was partial precooked, frozen and packed in bags by the supplier for easier handling. The ground beef was re-blanching at the FMT facility to avoid excessive weight loss during the retort process and thinning of the sauce. Also, the precooking/blanching process removed excessive fat and blood, which otherwise might yield an unacceptable dark product.

The cream sauce was made according to the recommended formula in the product specification with the exception that the starch quantity was reduced from 6% to 5.5%. The three main ingredients: "Starch", "Dry Cream" and "Shortening" were manufactured by respectively National Starch, Bridgewater NJ (Purity W or ThermTex), Quality Ingredients, Burnsville MN (Quali-Cream 7211) and Kerry Inc, Beloit WI (NDX-112 V, Item No. I1529).

The trays used in these experiments were manufactured by Rexam Containers, Union MO and are identified as "Military Steam Table Tray, Type I". The tray weighs approximately 155 grams with a minimal wall thickness of 0.037".

The tray was sealed under vacuum conditions with a Quad laminate film. The film was manufactured by Smurfit Flexible packaging, Schaumburg, IL and is identified as "LC Flex 70466, Green".

#### **3.2. Process Description**

The cream sauce was made in a jacketed Groen Kettle, equipped with high speed mixer and scrape surface agitator using the following procedure:

- ☐ Mix required quantity of starch in small quantity of cold water and mix vigorously to form a thin slurry.
- ☐ Add remaining quantity of cold water to kettle.
- ☐ Add Dry Cream to kettle and mix vigorously (speed setting: 2) till all dissolved.
- ☐ Add remaining ingredients (except starch slurry) to kettle and mix while heating kettle till product reaches 180 F to 190 F. Use high heat setting
- ☐ Add starch slurry and the final mixture should be heated to 180 F to 190 F and held at this temperature for 5 minutes. (Use low heat setting once 180 F is reached)
- ☐ Cool down the sauce to 90 F, pump into buckets and refrigerate.

It should be noted that the static retort samples were made with a Purity-W starch from National Starch, while the rotational retort samples were made with a ThermTex starch from National Starch. The TermTex starch does develop its final viscosity during the retort process and can therefore shorten the process time significantly

The Beef was cooked in boiling water and then drained. Depending on the use, the beef was either directly used or rinsed/cooled down and refrigerated for later use.

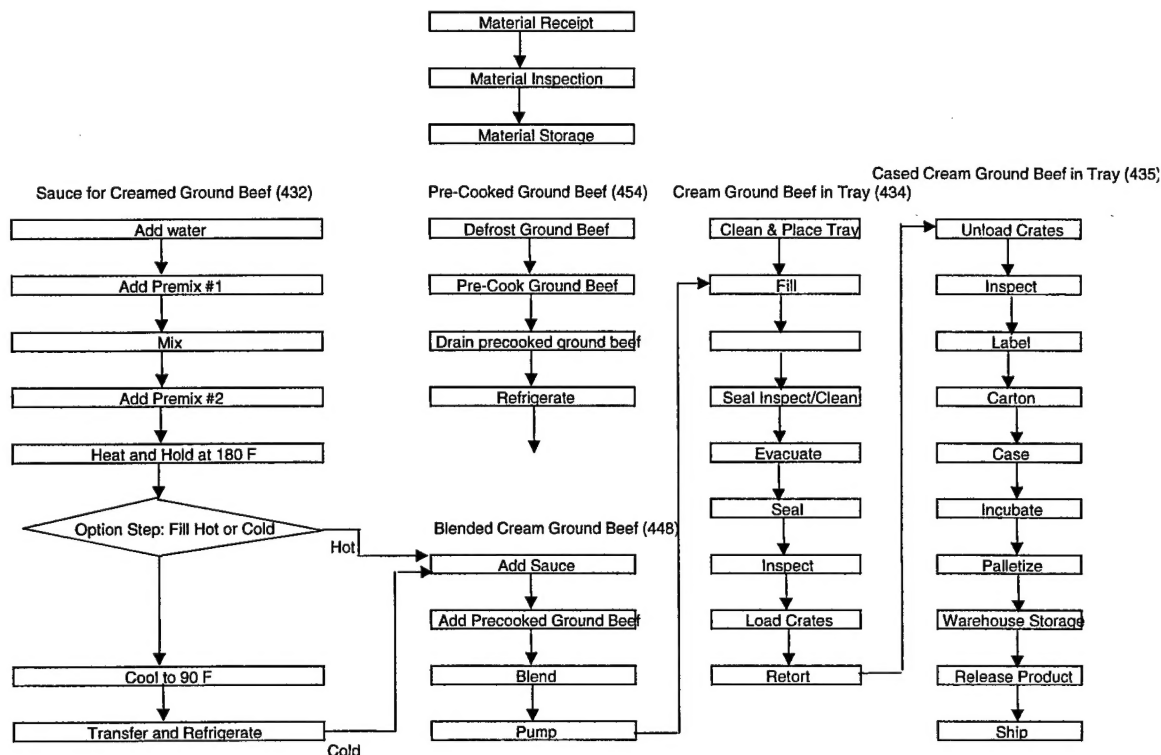

The Creamed Ground Beef was made in the Crazy Kettle by adding first the sauce and then the beef.

- ☐ Add precooked ground beef to the sauce and mix with till uniformly blended
- ☐ Pump blend to the Raque single piston filler hopper as needed.

The trays were placed on the filling conveyor of the Raque Heat Seal Line. The Raque Single Piston Filler filled the tray to a net weight of 92 oz. The trays were then conveyed to the Raque Heat Sealer and automatically loaded in the carriers of the sealer. Once in the carrier, the seals were inspected and when necessary wiped. The trays were conveyed at a speed of 8 trays/min. while seal conditions were maintained at 412 F for 3.5 seconds. The vacuum condition was controlled by a vacuum timer that opened a vacuum valve for a preset duration.

### Process Flow Sheet Creamed Ground Beef

The Creamed Ground Beef were packaged on Raque Heat Seal packaging line under various vacuum conditions. The objective of the production run was to seal product samples with different residual gas levels:

- 150 cc headspace
- 250 cc headspace
- 350 cc headspace

After the product was sealed in the containers, it was sterilized in either a still a full water immersion retort process, or a rotational full water immersion retort process. The process for a still retort was based on a process determined by a process authority on worst case scenario. However, due to the significant impact of residual gas on the heating process in a rotating heating process, on-line heat penetration was performed on seven production trays during each rotational retort process. The cook time was terminated once the  $F_0$  of 7.0 minutes was reached. This resulted into products that had seen a total lethality of at least 11 minutes (additional lethality was accumulated during the cooling process). Had we followed the filed process that was determined by the process authority based on worst case scenario's (30 cc headspace and P-W starch), our process would have been significant longer (~80 minutes).

Each container was visually inspected after the retort process, inserted into a carton sleeve and packed in a lined shipping case

### 3.3. Production Data

This product was packaged and sterilized on 8/23/01, 8/29/01 and 8/30/01

#### 3.3.1. Packaging Data
